Contra lateral hearing loss as an effect of venous congestion at the ipsilateral inferior colliculus after microvascular decompression: report of a case

Christian Strauss, Ramin Naraghi, Barbara Bischoff, Walter J Huk, Johann Romstöck

Abstract

Contra lateral hearing loss after surgical procedures within the cerebellopontine angle is rarely seen and its pathophysiological background is not yet understood. A patient with contra lateral hearing loss after microvascular decompression for trigeminal neuralgia is described. Ipsilateral brainstem auditory potential (BAEP) monitoring and facial nerve EMG did not show major abnormalities. During otherwise uneventful and successful surgery a branch of the petrosal vein was sacrificed to widen the access to the trigeminal root exit zone. On the third postoperative day the patient complained about contra lateral hearing loss, which was verified by audiometry. Contra lateral BAEPs showed low amplitudes and delayed interpeak latencies. Brain CT was normal. Brain MRI on the 8th postoperative day disclosed abnormal signals within the ipsilateral inferior colliculus. Intravenous heparinisation was performed and hearing slowly recovered over a 3 month period. Results from this patient offer a pathophysiological mechanism for contra lateral hearing loss after cerebellopontine angle surgery, illustrate the importance of venous drainage preservation, gives evidence about the generation of BAEP components within the contra lateral brainstem, and stresses the importance of intraoperative BAEP monitoring.

Case report

A 52 year old woman was admitted for microvascular decompression in typical V3 trigeminal neuralgia on the right side. A preoperative audiogram showed bilateral normal hearing. Brain MRI showed an arterial loop of the superior cerebellar artery with compression of the trigeminal nerve root exit zone and normal brain stem anatomy at the pontomesencephalic junction (fig 1). Microvascular decompression was uneventful except for dissection of the pontotrigeminal vein, proximal to the superior petrosal vein complex. Intraoperative ipsilateral BAEPs showed no abnormalities, except for a minor temporary latency shift of wave V. The use of insert earphones with a 20 cm silicone tube extension resulted in a peak delay of 0.60 ms, compared with conventional headphones. After surgery the neuralgia resolved completely, but on the third postoperative day the patient complained of contra lateral hearing loss. Audiometry showed a profound contra lateral pancochlear hearing loss with a pure tone average (PTA), calculated at 500, 1000, 2000, and 3000 Hz of 69 dB predominantly in the lower frequency range and normal hearing on the operated side (fig 2). Cranial CT was normal. Contra lateral BAEP obtained with insert earphones and a stimulation intensity of 95 dB normal hearing level showed low amplitudes throughout peaks I to V, loss of components, and a discrete delayed interpeak latency III-V of 2.16 ms compared with 1.81 ms (laboratory control group, table). No major abnormalities were seen on ipsilateral BAEP (fig 3, table). Intravenous medical treatment consisting of hydroxyethylstarch, lidocaine, prednisolone, and pentoxifyllin was given according to a treatment protocol for a total of 10 days. Control audiometry, performed on the 8th postoperative day, showed further deterioration with a PTA of 78 dB (fig 2). Brain MRI on the same day showed a hyperintense signal below the level of the inferior ipsilateral inferior colliculus consistent with venous congestion (fig 1). The patient was started on intravenous heparin (25 000 IU/24 h) for 11 days and hearing showed slight improvement during the subsequent days (fig 2). Three months after surgery BAEP latencies and amplitudes had improved, hearing had further improved with a PTA of 65 dB.
and recovery of speech discrimination (fig 2). Brain MRI showed partial resolution of the lesion.

Discussion

Profound contralateral hearing loss after cerebellopontine surgery can be a devastating complication for a patient, particularly in surgery for acoustic neurinoma. Barker and Jannetta reported one contralateral hearing loss in 1185 cases of microvascular decompression for trigeminal neuralgia. In surgery for acoustic neurinoma its incidence was found to be 1.3%, considering a loss of more than 20 dB as significant. Its pathophysiological mechanism is not yet fully understood. Brainstem shift, brainstem oedema, labyrinthine fluid imbalance due to CSF release and even a contralateral sympathetic labyrinthitis due to

Figure 2 Preoperative and postoperative serial pure tone audiograms of the contralateral ear. Normal hearing is documented before surgery (left). Profound hearing loss with complete loss of speech discrimination is demonstrated on the 4th postoperative day (12 July 1999), which gradually worsened despite vasoactive therapy (16 July 1999), and recovered after heparinisation. An audiogram 3 months after surgery documents further recovery (right).
injury of the ipsilateral labyrinth after translabyrinthine resection of acoustic neuromas have been discussed as possible causes. The presented case with intraoperative dissection of the pontotrigeminal vein, which receives drainage from the lateral mesencephalic vein, the late onset of symptoms on the 3rd postoperative day, the postoperative MRI showing abnormal signals below the level of the ipsilateral inferior colliculus, and the clinical recovery after heparinisation clearly point to the venous drainage system of the superior petrosal vein as the most likely cause for contralateral hearing loss. The venous drainage system of the superior petrosal vein has received little attention in the surgical management of cerebellopontine lesions. Due to its variabili-

ity and the richness of collaterals it is difficult to attribute morbidity specifically to the venous system. Matsushima et al in 1989 investigated the superior petrosal vein complex and identified three different groups (medial, intermediate, lateral) with one to three singular veins, the medialmost tributary of which can be sacrificed. McLaughlin et al routinely divide the superior petrosal vein complex during microvascular decompression for trigeminal neuralgia without adverse effects. Preservation of the superior petrosal vein during cerebellopontine angle surgery is usually not specifically considered, although its potential danger has been described several times. Sweet and Poletti, in their retrospective analysis of microvascular decompression procedures, performed in 49 different neurosurgical services, attributed four complications to “coagulation of essential veins draining the brainstem”. In cases with presumably normal anatomies, thrombosis or injury of the superior petrosal sinus is reported to cause significant brainstem morbidity, as in a recently published case of Raymond’s syndrome after superior petrosal sinus sampling for diagnostic investigation in Cushing’s syndrome, and in a case of microvascular decompression with transient pendular hallucinosis after dissection of the superior petrosal vein complex. Dissection of the pontotrigeminal vein, which receives drainage from the lateroposterior aspect of the mesencephalon including the colliculi via the lateral mesencephalic vein can certainly be the cause for contralateral hearing loss in the reported case. The variability of venous drainage patterns to the pons and medulla cautions against drawing conclusions from a singular case; however, the sacrifice of draining veins can be associated with cranial nerve dysfunction. Intraoperative BAEP monitoring during surgical procedures within the cerebellopontine angle is usually limited to the ipsilateral side. Venous congestion would most likely not have been seen by contralateral stimulation, especially as the clinical manifestation of contralateral hearing loss did not occur until the 3rd postoperative day.

This case further enhances the ongoing discussion about the generation of waves ipsilaterally or contralaterally. The profound contralateral hearing loss, the MRI documentation of an ipsilateral brainstem lesion below the level of the inferior colliculus, and the distorted low amplitude waveforms after contralateral stimulation with surprisingly little III-V IPL shift, give evidence for a significant contribution of crossed pathways to BAEPs. As the cochlear pathway crosses at the level of the corpus trapezoidum to the contralateral side, contralateral peak V analysis should be included in the protocol for ipsilateral monitoring of cochlear nerve function. This is particularly important in acoustic neuroma surgery with distorted potentials, in which often ipsilateral peaks beyond wave I become poorly distinguishable during tumour removal.
