Excitability properties of motor axons in patients with spontaneous motor unit activity

M C Kiernan, I K Hart, H Bostock

Abstract

Objectives—Measures of nerve excitability provide information about biophysical properties of peripheral axons in disease states. One measure, the strength-duration time constant ($\tau_{\text{SD}}$), was previously reported to be prolonged in motor axons of patients with acquired neuromyotonia. The present study used a new protocol that applies a more comprehensive and sensitive panel of measures of axonal excitability, to determine firstly whether changes in $\tau_{\text{SD}}$ were present in a group of patients with evidence of spontaneous motor unit activity; and secondly, if such changes in $\tau_{\text{SD}}$ were present, whether other parameters of axonal excitability were affected, to clarify the mechanism of the change in $\tau_{\text{SD}}$.

Methods—Eleven patients with both symptoms and EMG evidence of spontaneous motor unit activity were studied. Eight patients had autoimmune associated acquired neuromyotonia (aNMT) and three had the cramp fasciculation syndrome. The protocol first measured stimulus-response behaviour using two stimulus durations (from which the distribution of strength-duration time constants was estimated), and then threshold tracking was used to determine threshold electrotonus to 100 ms polarising currents, a current-threshold relation (indicating inward and outward rectification), and the recovery of excitability after supramaximal activation.

Results—The results were compared with previously published normal data. The value for $\tau_{\text{SD}}$ of motor axons in the patient group was 0.43 (0.02) ms (mean (SEM)), identical with the control value. Most other indices of axonal excitability, including those dependent on fast potassium channels, were also found to be normal. When compared with age matched controls however, the patients with acquired neuromyotonia had significantly greater late subexcitability after an impulse, greater excitability overshoots after depolarisation or hyperpolarisation, and more accommodation.

Conclusions—No clear evidence for the mechanism of ectopic discharge in these patients was obtained, probably because the activity was generated focally, and more often at the motor nerve terminals. The unexpected finding of increased excitability overshoots and accommodation compared with age matched controls, suggests a relative up regulation of slow potassium conductance, possibly as a consequence of the continuous motor unit activity.

Keywords: excitability; spontaneous activity; fasciculation; cramp

Fasciculation and cramp are common manifestations of neurological disease and may be caused by peripheral nerve hyperexcitability. In a recent study on patients with acquired neuromyotonia (aNMT), a condition attributed to nerve hyperexcitability, it was reported that the strength-duration time constant ($\tau_{\text{SD}}$) of motor axons was prolonged. Some of these patients expressed antibodies to neuronal voltage-gated potassium channels (VGKC), thought to be involved in the pathogenesis of this disease, and it was hypothesised that the increase in $\tau_{\text{SD}}$ was also caused by a functional blockade of VGKC by antibodies. The mechanism whereby anti-VGKC antibodies might increase $\tau_{\text{SD}}$ is not clear. Strength-duration time constant is a membrane time constant inferred from the relation between threshold current and stimulus duration. It has been defined as the ratio between the minimum charge threshold and resting membrane $\tau_{\text{SD}}$. Studies of $\tau_{\text{SD}}$ have shown that it is a nodal property, depending partly on the passive membrane time constant (the product of nodal capacitance and resting resistance) and partly on voltage-dependent membrane properties, particularly a persistent Na$^+$ conductance active at subthreshold potentials.

Membrane depolarisation increases $\tau_{\text{SD}}$, as although the passive time constant is reduced by an increase in K$^+$ conductance, this effect is outweighed by the activation of Na$^+$ channels.

Thus blocking nodal K$^+$ channels active at the resting potential could increase $\tau_{\text{SD}}$ directly, by increasing nodal resistance, whereas blocking either nodal or internodal K$^+$ channels would cause membrane depolarisation and increase $\tau_{\text{SD}}$ by activating Na$^+$ channels.

However, the anti-VGKC antibodies in aNMT are thought to be directed against fast K$^+$ channels, which contribute little to nodal conductance. These channels are found in their greatest number in the paranodal and juxtaparanodal regions, where they can contribute to the resting potential, but where access of antibodies is restricted. Further information about the mechanism of the increase in $\tau_{\text{SD}}$ should be obtainable from other excitability measurements sensitive to mem-
branched potential, and/or K\(^+\), or both conductances, such as the recovery cycle after an impulse and threshold electrotonus.\(^{12}\) Tomimitsu et al have reported finding anti-VGKC antibodies capable of suppressing K\(^+\) currents not only in patients with aNMT, but also in patients with myokymia of unknown origin.\(^{13}\) The question therefore arose as to whether patients with such clinical syndromes associated with nerve hyperexcitability also demonstrated changes in axonal membrane properties. The current study was undertaken to determine whether changes in \(\tau_{SD}\) were present in a group of patients with evidence of spontaneous motor unit activity, and if so, to determine how other parameters of axonal excitability were affected, to clarify the mechanism of the change in \(\tau_{SD}\). In addition, the study was the first to assess the utility in the clinical setting of a newly described method designed to measure multiple measures of axonal excitability.\(^{14}\)

**Patients and methods**

Studies were performed on 11 patients (eight men, three women, aged 37–67 years). All patients gave informed consent and the study was approved by the South Sefton research ethics committee (Walton Centre). No patients were taking immunosuppressive drugs. Patients stopped taking medication for symptomatic control of their cramp and muscle twitching 1 to 7 days before testing (carbamazepine five patients, sodium valproate two patients, phenytoin one patient, lamotrigine one patient, no therapy two patients).

Patients were recruited from a specialised neuromuscular outpatient clinic having presented with symptoms suggestive of continuous motor unit activity including muscle cramps, twitching, and stiffness, affecting both proximal and distal muscle groups in more than one limb. In each patient there was EMG evidence of nerve hyperexcitability in at least one affected muscle. Most (eight patients) demonstrated the characteristic EMG discharges present in aNMT—namely, doublet, triplet, or multiplet single motor unit discharges having a high intraburst frequency of between 40–400/s.\(^{2,7}\) An example is illustrated in fig 1 (lower plot). The remaining three patients had generalised fasciculation on EMG in fig 1 (lower plot). The remaining three patients had generalised fasciculation on EMG and the clinical diagnosis was the cramp fasciculation syndrome (CFS).\(^{15}\) Nerve conduction studies were within normal limits for each of the patients. No patient had a family history of muscle overactivity.

All eight patients with aNMT had evidence of autoimmune dysfunction. Serum samples from all 11 patients were tested using a \(^{125}\)I-dendotoxin radioimmunoprecipitation assay for anti-VGKC antibodies, which has a sensitivity of about 50%.\(^{2}\) Three patients with aNMT were positive: one at high titre (382 pmol/l) and two at low positive titres (100–200 pmol/l). Eight patients were negative (titre <100 pmol/l). The five patients with aNMT seronegative for anti-VGKC antibodies all had other findings suggestive of an immune disorder. Two patients had rheumatoid disease with high titre rheumatoid factor. One patient’s aNMT improved both clinically and on serial EMG recordings after plasma exchange. One patient had undergone thymectomy for a lymphocytic thymoma and had high titre anticholinergic receptor antibodies without clinical or EMG evidence of myasthenia gravis. One had paraneoplastic aNMT as she was found to have a small cell lung carcinoma 3 months after the date of the recordings.\(^{17}\) In the three patients with CFS, extensive serum autoimmune screens were normal.

Studies were performed using a recently described protocol designed to measure a number of different nerve excitability parameters rapidly.\(^{16}\) Compound muscle action potentials were recorded from thenar muscles using surface electrodes over the abductor pollicis brevis, with the active electrode at the motor point and the reference on the proximal phalanx. The EMG signal was amplified (gain 1000, bandwidth 1.6 Hz to 2 kHz) and digitised by computer (486 PC) with A/D board (DT2812, Data Translation Inc, 100 Locke Drive, Marlboro, MA 01752–1192, USA), using a sampling rate of 10 kHz. Stimulus waveforms generated by the computer were converted to current with a purpose built constant current stimulator (maximum output ± 50 mA). The stimulus currents were applied via non-polarisable electrodes (Red Dot, 3M Health Care, D-46325 Borken, Germany), with the active electrode over the median nerve at the wrist, and the reference electrode about 10 cm proximal over muscle. Stimulation and recording were controlled by new software, written in BASIC (QTRAC version 4.3, copyright Institute of Neurology, London, UK with multiple excitability protocol TRONDHM).

Test current pulses of 0.2 ms or 1 ms were applied regularly at 1 s intervals, and combined with suprathreshold conditioning stimuli or subthreshold polarising currents as required. A complete recording sequence is illustrated in figure 1. The amplitude of the compound muscle action potential (CMAP) was measured from baseline to negative peak. For all tracking studies, the target CMAP was set to be 40% of the peak response. Skin temperature was monitored close to the stimulation site and was kept constant above 32°C.

Stimulus-response curves were recorded separately for test stimuli of durations 0.2 ms and 1 ms. The stimuli were increased in 6% steps, with two responses averaged for each step, until three averages were considered maximal (fig 1 A). The stimulus-response data were used for several purposes. Firstly, the 1-ms peak response was used to set the target submaximal response (40% of peak) for threshold tracking for the remainder of the study. Secondly, the slope of the 1 ms stimulus-response curve was used in conjunction with the tracking error (deviation from the target) to optimise the subsequent threshold tracking. Finally, when the data were analysed, the ratio between the 0.2 ms and 1 ms stimuli required to evoke the same responses were used to estimate the strength-duration time.
constants and rheobases of axons of different threshold.

Prolonged subthreshold currents were used to alter the potential difference across the internodal axonal membrane, a process referred to as electrotonus. The changes in threshold associated with electrotonus normally have a similar time course to the changes in membrane potential and are known as threshold electrotonus. In the present protocol, test stimuli of 1 ms duration were used to produce the target CMAP (40% of maximal). Threshold tracking was used to record the changes in threshold induced by subthreshold polarising currents, 100 ms in duration, set to be +40% (depolarising) and -40% (hyperpolarising) of the control threshold current. The three stimulus combinations were tested in turn: test stimulus alone (to measure the control threshold current), test stimulus+depolarising conditioning current, and test stimulus+hyperpolarising conditioning current. Threshold was tested at 26 time points (maximum separation 10 ms) before, during, and after the 100 ms conditioning currents. Each stimulus combination was repeated until three valid threshold estimates were recorded, as judged by the response being within 15% of the target response, or alternate responses being either side of the target (fig 1 B).

The current-threshold relation was tested with 1 ms pulses at the end of subthreshold polarising currents lasting 200 ms (fig 1 C). The polarising current was altered in a ramp fashion from +50% (depolarising) to -100%

Figure 1  Example of data recorded from each patient: upper three plots show amplitudes of stimuli, CMAP responses and delay between conditioning and test stimuli for four segments of recording A-D. The lowest plot illustrates one EMG trace in 14, during the prestimulus period, to show spontaneous motor unit activity, with the sweep separation corresponding to an amplitude measure of 30 µV. (A) Stimulus-response behaviour, stimulus duration 0.2 ms, then 1.0 ms. (B) Threshold electrotonus recording with 100 ms conditioning stimuli, 40% and -40% of threshold. (C) Current/threshold recording with 200 ms conditioning stimuli varied from 50% to -100% of threshold. (D) Recovery cycle, threshold changes 200 to 2 ms after single, supramaximal stimulus.
Excitability properties of motor axons in patients with spontaneous motor unit activity

59

(1.9) years, temperature 32.3 (0.2)

(normal controls in the previous study (age 39.4 (40.7 (1.9) years, mean (SEM)) and skin tem-

peratures above 31°C) from the patients with ANM. Excit-

ation of the curve towards the top right results

Curves for each of the patients studied were

are normal in shape, because the normalised traces

in figure 2 B all fall within the normal limits, as

do the stimulus-response slopes in figure 3 B.

There was therefore no evidence of axons being

affected non-uniformly by the disease. The peak

CMAP amplitudes were smaller on average,

than the normal controls (figs 2 A, 3 B),

but this difference was not significant when the

comparison was made with age matched controls.

One patient with CFS had an abnor-

mally high threshold (fig 2 A) and rheobase (fig

3 A), and there was a tendency for the patients
to have higher thresholds on average than the

controls (fig 2 A). However, the difference from

age matched controls was not significant at the

1% level, and was in the opposite direction
from one which could account for the continu-

ous motor unit activity.

The current-threshold relations for each

patient, calculated using the normalised

threshold changes at the end of 200 ms current

pulses, are plotted in fig 2 C. For each level of

conditioning current, from +50% to -100% of

the control threshold, the threshold change was

measured, and the percentage threshold reduc-
tion plotted, depolarisation to the right and

hyperpolarisation to the left. The current-
threshold relation resets the rectifying proper-
ties of the axon (both nodal and internodal

axolemma), and the slope of the curve can be

used to provide an estimate of the threshold

analogue of input conductance. The steepen-
ing of the curve towards the top right results

from outward rectification, an accommodative

response to the depolarising current, associated

with the activation of fast and slow K+ channels, the steeper the plot the greater the

accommodation (rectification).

The less prominent steepening towards the bottom left of the figure represents accommodation to the hyperpolarising current due to inward rectifi-
cation, and thereby represents activation of the
hyperpolarisation-activated conductance, I_H.22
Curves for each of the patients studied were

within the normal range, as were the minimum

and resting slopes of the current/threshold

relationship (fig 3 C). This suggests that the

rectifying properties of the nerves studied

remained intact.14

Strength-duration time constant was calcu-
lated from the thresholds measured using test

pulses of two durations, 0.2 and 1.0 ms. Calcu-
lations were performed for different axonal

populations, using the normalised stimulus-

response data as in figure 2 B. Nine populations

were used, starting from axons contributing to

the recording three patients had evidence of

spontaneous activity in the abductor pollicis

brevis muscle. In one subject doublet dis-

charges were recorded throughout the study,

illustrated in fig 1.

Primary data from all the patients are plotted

in fig 2, and selected pairs of parameters are

plotted as scatter plots in fig 3.14 Open circles
differentiate the small CFS group in figs 2 A

and 3, and the dotted lines in each figure indi-
cate the 95% confidence intervals for a normal

subject, based on the 29 controls in the

previous study.14

The stimulus-response curves in fig 2 A are

normal in shape, because the normalised traces

were used, starting from axons contributing to

(hyperpolarising) of the control threshold in

10% steps. As with the conventional threshold

electrotonus protocol, stimuli with condition-
ing currents were alternated with test stimuli

alone, and each stimulus combination was

repeated until three valid threshold estimates

were obtained.

The final part of the protocol recorded the

recovery of excitability after a supramaximal

conditioning stimulus (fig 1 D). These changes

were recorded at 18 conditioning test intervals,

decreasing from 200 to 2 ms in roughly

geometric progression. Three stimulus combi-
nations were tested in turn: (1) unconditioned

test stimulus (of 1 ms duration) tracking the

control threshold, (2) supramaximal condi-
tioning stimulus (1 ms duration) alone, and (3)

conditioning+test stimuli. The response to (2)

was subtracted on line from the response to (3)

before the test CMAP was measured, so that

the conditioning maximal CMAP did not con-
taminate the measured response when the con-

ditioning test interval was short. Each stimulus

combination was repeated until four valid

threshold estimates were obtained.

Rheobase current and I_R were calculated off

line from the stimulus-response data. The

strength-duration curve for peripheral nerve

axons is hyperbolic, not exponential, and the

best curve fit for strength-duration data comes

from Weiss' equation. This empirical law

relates stimulus charge (threshold current

multiplied by its duration) to stimulus duration

and may be estimated reliably from the thresh-

olds for just two pulse durations.15-20

Values for the excitability parameters ob-
tained in the current study were compared with

normative data established in a previous study

where testing conditions were identical.14

However, some excitability properties change

with age and/or temperature. Whereas the

er three patients with CFS were similar in age

(40.7 (1.9) years, mean (SEM)) and skin tem-

peratures (32.5 (0.5)°C) to the full group of

normal controls, the normalised traces

were used, starting from axons contributing to

www.jnnp.com
the responses between 5%-15% of maximal, then 15%-25%, further increasing in 10% batches up to the maximum of 85%-95%. These nine $\tau_{\text{SD}}$s were plotted against their corresponding CMAP responses in fig 2 D, and all patient $\tau_{\text{SD}}$ measurements fell well within the normal limits. This is also shown in fig 3 A, where $\tau_{\text{SD}}$s are plotted against rheobase for responses 35%-45% of maximal. The value for $\tau_{\text{SD}}$ of motor axons in the patient group was 0.43 (0.02) ms (mean (SEM)). This value is the same as that reported for the control group (0.43 (0.02) ms; mean (SEM)) and very similar to that reported elsewhere for normal nerve (0.46 (0.13) ms, mean (SD)).

Significantly, there was no evidence for the high $\tau_{\text{SD}}$ reported by Maddison et al in some of their patients with aNMT. As with the thresholds for a 50% maximum CMAP in fig 2 A, the rheobases in fig 3 A were higher than normal on average, and well above the normal range in one patient with CFS. A technical explanation, perhaps related to the distance of the stimulating electrode from the underlying motor fascicles, may have been responsible, as nerve conduction studies were normal in this patient, as in the others.

Figure 2  Excitability data for all subjects superimposed on the 95% confidence intervals for a member of the control population taken from a previous study (broken ellipses). (A) Absolute stimulus-response relations indicated by plotting half maximal CMAP amplitude v stimulus for half maximal response (log-log coordinates); (B) normalised stimulus-response relations; (C) current-threshold relation; (D) distribution of strength-duration time constants; (E) threshold electrotonus; (F) recovery cycle. Threshold tracking performed using a test pulse of 1 ms duration. In plot A, filled circles=patients with aNMT, open circles=patients with CFS.
The changes in excitability associated with threshold electrotonus are illustrated in fig 2 E. As in previous studies, the changes in threshold are plotted as threshold reductions, with responses to depolarising currents upwards, as is normal for electrotonus. The fast changes in threshold that occur at delays of 0 and 100 ms are due to the rapid (<1 ms) changes in potential occurring at the nodes of Ranvier at the onset and offset of the polarising currents. The slower excitability changes are caused by slower potential changes occurring passively on the internodal membrane, and by ion channels with slow kinetics, especially slow potassium channels at the nodes. The traces from the patients all fell within the normal limits, and conventional indices derived from the threshold electrotonus recordings, including the early depolarising response TEd (10–20 ms) which can reflect fast potassium channel activity, also fell within normal limits (fig 3 E).

To complete the protocol, the recovery cycle (the absolutely and relatively refractory periods, the supernormal period, and the late subnormal period) was recorded. In fig 2 F the threshold changes are plotted with a logarithmic time scale, to show more clearly the early events in the cycle. The traces from the patients mostly fell within the normal limits, but between 20 and 70 ms, the late subexcitability was greater than normal in one patient with aNMT and less than normal in a patient with CFS (fig 3 F). The remaining patients

threshold electrotonus that is, the undershoot after depolarising ability that followed a depolarising current—
aNMT. Statistically the most significantly they were abnormal in the patients with

fig 3), derived from the data in fig 2, to see if excitability parameters (in addition to the 12 in

malities in subexcitability, we tested another 10 membrane properties underlying this abnor-

p=0.35).

matched controls (−23.0 (1.7)%, n=8, p=0.002). Even when the outlying patient was omitted, the aNMT group had signifi-
cantly higher subexcitability (18.0 (0.8)%, n=7) than the matched controls (p=0.001). By contrast, although there was a tendency for the superexcitabilities of the patients with aNMT (−20.9 (1.3)%, n=8) to be less than in the full control group (−25.3 (1.0)%, n=29, p=0.04), they were not significantly different from the matched controls (−23.0 (1.7)%, n=8, p=0.35).

To obtain further information about the membrane properties underlying this abnormality in subexcitability, we tested another 10 excitability parameters (in addition to the 12 in fig 3), derived from the data in fig 2, to see if they were abnormal in the patients with aNMT. Statistically the most significantly abnormal parameter tested was the subexcitability that followed a depolarising current—that is, the undershoot after depolarising threshold electrotonus. The value of this parameter in patients with aNMT (−21.5 (0.9)%, n=8) was significantly higher than in the matched control group (−15.8 (0.7)%, n=8, p=0.0001), although not significantly differ-
ent from the full control group (−19.3 (0.7)%, n=29, p=0.13), as this parameter varies with age and temperature. Similarly, the threshold overshoot (increased excitability) after a hyperpolarising current was significantly greater in patients with aNMT (19.2 (1.4)%, n=8) than in age and temperature matched controls (14.0 (0.7)%, n=8, p=0.005), but not in comparison with the unmatched controls (16.5 (0.7)%, n=29, p=0.07). These abnor-
malities in the overshooting of electrical excitability after a displacement of membrane potential, whether by a spike or by applied cur-

citability of the aNMT group (19.4 (1.5)%), mean (SEM), n=8) was abnormally high, whether compared with the full control group (14.7 (0.7)%, n=29, p=0.006) or with age and temperature matched controls (12.2 (1.1)%, n=8, p=0.002). Even when the outlying patient was omitted, the aNMT group had signifi-
cantly higher subexcitability (18.0 (0.8)%, n=7) than the matched controls (p=0.001). By contrast, although there was a tendency for the superexcitabilities of the patients with aNMT (−20.9 (1.3)%, n=8) to be less than in the full control group (−25.3 (1.0)%, n=29, p=0.04), they were not significantly different from the matched controls (−23.0 (1.7)%, n=8, p=0.35).

To obtain further information about the membrane properties underlying this abnormality in subexcitability, we tested another 10 excitability parameters (in addition to the 12 in fig 3), derived from the data in fig 2, to see if they were abnormal in the patients with aNMT. Statistically the most significantly abnormal parameter tested was the subexcitability that followed a depolarising current—that is, the undershoot after depolarising threshold electrotonus. The value of this parameter in patients with aNMT (−21.5 (0.9)%, n=8) was significantly higher than in the matched control group (−15.8 (0.7)%, n=8, p=0.0001), although not significantly differ-
ent from the full control group (−19.3 (0.7)%, n=29, p=0.13), as this parameter varies with age and temperature. Similarly, the threshold overshoot (increased excitability) after a hyperpolarising current was significantly greater in patients with aNMT (19.2 (1.4)%, n=8) than in age and temperature matched controls (14.0 (0.7)%, n=8, p=0.005), but not in comparison with the unmatched controls (16.5 (0.7)%, n=29, p=0.07). These abnor-
malities in the overshooting of electrical excitability after a displacement of membrane potential, whether by a spike or by applied cur-

citability of the aNMT group (19.4 (1.5)%), mean (SEM), n=8) was abnormally high, whether compared with the full control group (14.7 (0.7)%, n=29, p=0.006) or with age and temperature matched controls (12.2 (1.1)%, n=8, p=0.002). Even when the outlying patient was omitted, the aNMT group had signifi-
cantly higher subexcitability (18.0 (0.8)%, n=7) than the matched controls (p=0.001). By contrast, although there was a tendency for the superexcitabilities of the patients with aNMT (−20.9 (1.3)%, n=8) to be less than in the full control group (−25.3 (1.0)%, n=29, p=0.04), they were not significantly different from the matched controls (−23.0 (1.7)%, n=8, p=0.35).

To obtain further information about the membrane properties underlying this abnormality in subexcitability, we tested another 10 excitability parameters (in addition to the 12 in fig 3), derived from the data in fig 2, to see if they were abnormal in the patients with aNMT. Statistically the most significantly abnormal parameter tested was the subexcitability that followed a depolarising current—that is, the undershoot after depolarising threshold electrotonus. The value of this parameter in patients with aNMT (−21.5 (0.9)%, n=8) was significantly higher than in the matched control group (−15.8 (0.7)%, n=8, p=0.0001), although not significantly differ-
ent from the full control group (−19.3 (0.7)%, n=29, p=0.13), as this parameter varies with age and temperature. Similarly, the threshold overshoot (increased excitability) after a hyperpolarising current was significantly greater in patients with aNMT (19.2 (1.4)%, n=8) than in age and temperature matched controls (14.0 (0.7)%, n=8, p=0.005), but not in comparison with the unmatched controls (16.5 (0.7)%, n=29, p=0.07). These abnor-
malities in the overshooting of electrical excitability after a displacement of membrane potential, whether by a spike or by applied cur-

Discussion

The present study has established that a proto-

col recently developed to record multiple measures of axonal excitability can be used in the clinical setting, is tolerable to the patient, and can be employed in an efficient manner. Using this protocol, we have shown that patients with immune-associated aNMT, or CFS, who have active symptoms and signs of nerve hyperexcitability, and in some cases EMG findings of spontaneous motor unit activity during the recordings, had no clear evi-
dence of axonal membrane hyperexcitability when compared with healthy control subjects.

It has been reported that aNMT, a measure of axonal excitability, can be prolonged in motor axons of patients with amyotrophic lateral sclerosis (ALS). More recently a similar finding was obtained in some patients with aNMT. Such an increase in \( t_{\text{SD}} \), may indicate membrane depolarisation. Alternatively it may occur by means of an increase in a persistent sodium conductance, or by paranodal demyelination.

In the study on patients with ALS, it was sug-
gested that a greater representation of a persistent Na\(^+\) conductance may be responsible for both the prolongation of \( t_{\text{SD}} \) and the develop-
ment of fasciculation. In patients with aNMT, it was proposed that in addition to the above mechanisms, anti-VGKC antibodies may contribute to the prolongation of \( t_{\text{SD}} \) recorded from motor axons by means of an indirect effect on axonal membrane properties. By contrast, the present study has found that in patients with similar clinical syndromes associated with spontaneous motor unit activity, no prolongation in the \( t_{\text{SD}} \) of motor axons was evident.

Strength-duration time constant is a nodal property of the axonal membrane. Voltage gated K\(^+\) channels are not uniformly distri-
buted along the axonal membrane. In aNMT the antibodies are thought to act against fast K\(^+\) channels, of which there are very few present in the nodal region. Their density is greatest in the paranodal region where, provided the myelin sheath is intact, they should be protected from circulating autoantibodies. Studies of the effects of 4-aminopyridine, a blocker of fast potassium channels, on the electrical properties of myelinated axons have shown that supereexcitability is increased, as is the early depolarising electrotonus, and there is
a small membrane depolarisation. There was no evidence of any such changes among our patients. By contrast with the fast K+ channels, there is a high density of slow K+ channels present at nodes of Ranvier, a site more accessible to immune attack. However, the excitability parameters that depend most on slow K+ channels—namely, the late subnormal phase in the recovery cycle, the accommodation that occurs with depolarisation during threshold electrotonus, and the undershoot in excitability that follows—were within the normal range and on average significantly greater in the patients with aNMT than in the age matched control group. These changes, which suggest a relative up regulation of slow K+ channels in these patients, could not account for the ectopic discharges. They might, however, indicate an adaptive response to the continuous motor unit activity. Recently differences in the same excitability parameters have been reported between median and peroneal axons, and the suggestion made that slow K+ conduc-
tance may depend on axonal discharge patterns or peak firing rates.11

WHERE DO THE ECTOPIC IMPULSES ORIGINATE?

These findings prompt questions about the nature and origin of the generator producing the ectopic motor activity that occurs in patients with aNMT and related syndromes. In aNMT, as in other immune mediated diseases, symptom severity and EMG findings can vary over time often in an unpredictable pattern. This may be one explanation why some previously studied patients have a prolonged \( \tau_{50} \) during a single, short period of recording while our and other similar patients do not.1 By implication, it is possible that the results using our protocol would be less uniform if testing were repeated serially in individual patients.

In the patients studied, no evidence of axonal hyperexcitability was detected, even when they had spontaneous activity in the abductor pollicis brevis during the testing, and regardless of their anti-VGKC antibody status or evidence of a systemic autoimmune diathesis. It seems unlikely that this lack of abnormality reflected an ongoing effect of the patient’s drug therapy, in most cases the anticonvulsant carbamazepine. All patients remained symptomatic, albeit to a lesser degree, even while taking medication. Furthermore, all patients ceased their medication from 1 to 7 days before testing, at which stage it was possible to record spontaneous activity during testing (fig 1). Finally, \( \tau_{50} \) has been found to be similar whether or not patients are taking carbamazepine.5

In the study by Maddison et al,3 some patients with aNMT had a prolonged \( \tau_{50} \) while others had values in the normal range. Moreover, there was no relation between the prolongation in \( \tau_{50} \) and the presence or absence of serum anti-VGKC antibodies, or the presence or absence of spontaneous motor unit activity during the recordings. These findings, taken together with our results, suggest that, as some other immune mediated neurological diseases
