Clinical study of 222 patients with pure motor stroke

A Arboix, I Padilla, J Massons, L García-Eroles, E Comes, C Targa

Abstract
The objective was to assess the frequency of pure motor stroke caused by different stroke subtypes and to compare demographic, clinical, neuroimaging, and outcome data of pure motor stroke with those of patients with other lacunar stroke as well as with those of patients with non-lacunar stroke.

Data from 2000 patients with acute stroke (n=1761) or transient ischaemic attack (n=239) admitted consecutively to the department of neurology of an acute care 350 bed teaching hospital were prospectively collected in the Sagrat Cor Hospital of Barcelona stroke registry over a 10 year period. For the purpose of the study 222 (12.7%) patients with pure motor stroke were selected. The other study groups included 218 (12.3%) patients with other lacunar strokes and 1321 (75%) patients with non-lacunar stroke.

In relation to stroke subtype, lacunar infarcts were found in 189 (85%) patients, whereas ischaemic lacunar syndromes not due to lacunar infarcts occurred in 12 (10.4%) patients (atherothrombotic stroke in 12, cardioembolic stroke in seven, infarction of undetermined origin in three, and infarction of unusual aetiology in one) and haemorrhagic lacunar syndromes in 10 (4.5%). Patients with pure motor stroke showed a better outcome than patients with non-lacunar stroke with a significantly lower number of complications and in hospital mortality rate, shorter duration of hospital stay, and a higher number of symptom free patients at hospital discharge. After multivariate analysis, hypertension, diabetes, obesity, hyperlipidaemia, non-sudden stroke onset, internal capsule involvement, and pons topography seemed to be independent factors of pure motor stroke in patients with acute stroke.

In conclusion, about one of every 10 patients with acute stroke had a pure motor stroke. Pure motor stroke was caused by a lacunar infarct in 85% of patients and by other stroke subtypes in 15%. Several clinical features are more frequent in patients with pure motor stroke than in patients with non-lacunar stroke.

Keywords: pure motor stroke; lacunar infarcts

Pure motor stroke is the most common and clinically best characterised of the lacunar syndromes. In this hospital based prospective study, we assessed the frequency of pure motor stroke caused by different stroke subtypes and the differential clinical features between pure motor stroke and other lacunar strokes. Demographic, clinical, neuroimaging, and outcome data of pure motor stroke and non-lacunar strokes were compared.

Patients and methods
Between 1986 and 1995, data from 2000 patients with acute stroke admitted consecutively to an acute care 350 bed teaching hospital in the city of Barcelona, Spain, were collected prospectively in a stroke registry. Transient ischaemic attacks were excluded. The study population consisted of 1761 patients with acute stroke. Subtypes of stroke were classified according to criteria of the Cerebrovascular Study Group of the Spanish Society of Neurology, which is similar to the National Institute of Neurological Disorders and Stroke classification. Definitions of cerebrovascular risk factors and lacunar syndrome (pure motor stroke, pure sensory stroke, sensorimotor stroke, ataxic hemiparesis, dysarthria-clumsy hand syndrome, and atypical lacunar syndromes) were those used in previous studies. Pure motor stroke was defined as a unilateral partial or complete paresis involving at least two of three areas (face, upper limb, or lower limb) of the body and no evidence of aphasia, apraxia, andagnosia, nor visual field defect, eye movement disturbance, ataxia, sensory loss, or evidence of bilateral weakness. Other lacunar syndromes were defined as producing pure sensory stroke, sensorimotor stroke, ataxic hemiparesis, dysarthria-clumsy hand, and atypical lacunar syndromes. Non-lacunar syndromes included all patients whose clinical picture did not conform with the preceding subgroups.

Lacunar syndromes diagnosed in 440 consecutive patients were collected. These included pure motor stroke in 222 patients, pure
sensory stroke in 72, sensorimotor stroke in 59, ataxic hemiparesis in 17, dysarthria-clumsy hand in 25, and atypical lacunar syndrome in 45. Data from the 222 patients with pure motor stroke were selected. In all patients, diagnoses were established after diagnostic studies were performed and were consistent with definite diagnoses coded on the patient’s discharge form. Atypical lacunar syndromes consisted of isolated dysarthria (n=24), hemichorea-hemiballismus (n=5), unilateral paramedial thalamic infarction (n=2), bilateral paramedial thalamic infarction (n=3), pure motor hemiparesis with transient subcortical aphasia (n=4), pure motor hemiparesis with transient internuclear ophthalmoplegia (n=4), and isolated hemiataxia (n=3). As defined in previous studies, pure motor stroke was attributed to a lacunar infarct, a cardioembolic infarction, an atherothrombotic infarction, a brain infarction of unusual aetiology, or a lacunar infarct of unknown cause.

All patients were admitted to hospital within 48 hours of stroke onset. Demographic characteristics, features of neurological examination, laboratory tests, chest radiography, and 12-lead electrocardiography were recorded. Brain CT was done within the first hospital week. Patients with negative results had a second CT during their stay in hospital or were studied by MRI (22% of patients). Other investigations included arterial digital subtraction angiography in 16% of patients, B mode echocardiography in 15%, carotid duplex scan in 14%, and lumbar puncture in 5%. Outcome data included mortality in hospital, degree of clinical disability at discharge, and neurological complications, cardiac events, respiratory events, urinary events other than urinary tract infection, vascular complications, gastrointestinal complications, and infectious complications.

Student’s t test and the χ² test (with Yate’s correction when necessary) were used to compare features of patients with pure motor stroke with those of patients with other lacunar syndromes as well as with those of patients with non-lacunar stroke. Variables related to pure motor stroke in the univariate analysis plus age and sex were studied in multiple regression models based on demographic and vascular risk factors and clinical, neuroimaging, and outcome variables, in which pure motor stroke was the dependent variable.

### Results

Of the 1761 patients with acute stroke, pure motor stroke was diagnosed in 222 (12.7%). Other lacunar strokes were found in 218 patients and non-lacunar strokes in the remaining 1321. Lacunar infarcts were found in 189 (85%) patients, whereas ischaemic lacunar syndromes not due to lacunar infarcts occurred in 23 (10.4%) patients (atherothrombotic stroke in 12, cardioembolic stroke in seven, infarction of undetermined origin in three, and infarction of unusual aetiology in one) and haemorrhagic lacunar syndromes in 10 (4.5%).

In the 222 patients with pure motor stroke, there were 128 men and 94 women, with a mean (SD) age of 72.7 (10.3) years. Hypertension and diabetes were the most common vascular risk factors. Non-sudden onset of symptoms was found in 50% of patients. Speech disturbances occurred in 39% of patients. Involvement of the internal capsule was the most frequent topography. The in-hospital mortality was 0.5% (n=1). Symptom free at hospital discharge was recorded in 43 (19.4%) patients. The mean duration of hospital stay was 13.7 (9.7) days.

There was a striking similarity between patients with pure motor stroke and patients with other lacunar strokes. However, limb weakness, involvement of the internal capsule, and middle cerebral artery topography were significantly more frequent in the pure motor stroke group, whereas sensory symptoms, thalamic involvement, and posterior cerebral artery topography were significantly more frequent in patients with other lacunar strokes. On the other hand, at univariate analysis, variables associated with pure motor stroke included male sex, hypertension, diabetes, obesity, smoking, hyperlipidaemia, non-sudden stroke onset, limb weakness, internal capsule involvement, pons involvement, and centrum

particularly early thrombolytic therapy,12 cause of implications for clinical management, source of embolism, intracerebral hemorrhage, mechanisms, such as atherosclerosis, cardiac failure, anticoagulation, sudden stroke onset, headache, dizziness, seizures, nausea, and vomiting, altered consciousness, sensory deficit, hemianopia, speech disturbances, basal ganglia involvement, medulla involvement, middle cerebral artery topography, and posterior cerebral artery topography. Patients with pure motor stroke showed a better outcome than patients with non-lacunar stroke with a significantly lower number of complications and in hospital mortality rate, shorter duration of hospital stay, and a higher number of symptom free patients at hospital discharge. After multivariate analysis, hypertension, diabetes, obesity, hyperlipidemia, non-sudden stroke onset, involvement of the internal capsule, and pons topography seemed to be independent factors of pure motor stroke in patients with acute stroke (table 1).

Discussion

Pure motor stroke accounted for 12.7% of cases in the stroke registry and constituted 50% of lacunar syndromes. In agreement with previous studies,13-16 pure motor stroke is a reliable clinical test for diagnosing lacunar infarction. Accordingly, the concept of the lacunar hypothesis is clinically valid and useful. Although pathological heterogeneity in patients with pure motor stroke was found in 15% of our patients, the present results support the theory that pure motor stroke is commonly due to lacunar infarcts resulting from small vessel disease.17 However, roughly one in every seven patients with pure motor stroke may be associated with underlying non-lacunar ischaemic mechanisms, such as atherosclerosis, cardiac source of embolism, intracerebral haemorrhage, or spontaneous subdural haematoma that may influence management. Thus, because of implications for clinical management, particularly early thrombolytic therapy,18 it is mandatory to establish the aetiological diagnosis of pure motor stroke to classify correctly the stroke subtype.

Our findings showed a striking similarity in demographic data, vascular risk factors, and outcome between pure motor stroke and other lacunar strokes. However, there were important differences between pure motor stroke and non-lacunar strokes. In the multivariate analysis, hypertension, diabetes, hyperlipidemia, and obesity were independent vascular risk factors significantly associated with pure motor stroke. Hypertension has been recognised as the single most important modifiable risk factor for acute stroke19 with a maximal frequency of presentation in lacunar infarcts.16 Diabetes is also a well known risk factor for lacunar infarction. Our results support the sufficient evidence to indicate that hypertension and diabetes have a direct effect on the occurrence of severe atherosclerotic stenosis of extracranial and intracranial arteries.15 Atherosclerosis and microangiopathy of coronary, peripheral, and cerebral arteries are often a complication of diabetes. Our results are in accord with those of a recent study20 in which history of diabetes and hyperlipidemia were important risk factors for patients with lacunar strokes. Our findings indicate that obesity may be a more potent risk factor for pure motor stroke and lacunar infarcts than previously considered. The implication of lipohyalinosis (vasculopathy mainly responsible for small sized lacunar infarcts) in the association of obesity and lacunar stroke should be assessed in further clinicopathological studies. The fact that cardiac embolism is an unlikely mechanism for lacunar infarction is the reason for the inverse association between pure motor stroke and atrial fibrillation, rheumatic heart disease, and congestive heart failure.

Non-sudden stroke onset16 was an independent factor associated with pure motor stroke, whereas speech disturbances, headache, and dizziness were inversely associated with pure motor stroke. A non-sudden onset of neurological deficit was seen in 50% of pure motor stroke and in 32% of non-lacunar strokes. A slow onset characterises many lacunar infarcts by contrast with the sudden onset of most cases of major atheromatous or cardioembolic strokes. Headache occurred rarely and was inversely associated with pure motor stroke. It has been shown that headache is more frequent in haemorrhagic than in ischaemic stroke, and among patients with ischaemic stroke, the lacunar infarcts accounted for the lowest frequency of headache.19 20 On the other hand, the lower frequency of speech disturbances in pure motor stroke may be due to the small lesion size and the more frequent topography at the subcortical level of the internal capsule or the pons and to a lower frequency of involvement of the territory of the middle cerebral artery compared with non-lacunar strokes.

The favourable outcome of patients compared with non-lacunar strokes was shown by a lower frequency of medical complications, in hospital mortality rate, and shorter duration of hospital stay. Patients with pure motor stroke showed significant spontaneous improvement with a higher frequency of symptom free at hospital discharge than patients with non-lacunar stroke.

We thank Drs M Balcells and M Oliveres for valuable participation in the study and Marta Pulido for editing the manuscript.

**1st Asia Pacific Forum on Quality Improvement in Health Care**

Three day conference
Wednesday 19 to Friday 21 September 2001
Sydney, Australia

We are delighted to announce this forthcoming conference in Sydney. Authors are invited to submit papers (call for papers closes on Friday 6 April), and delegate enquiries are welcome.

The themes of the Forum are:
- Improving patient safety
- Leadership for improvement
- Consumers driving change
- Building capacity for change: measurement, education and human resources
- The context: incentives and barriers for change
- Improving health systems
- The evidence and scientific basis for quality improvement.

Presented to you by the BMJ Publishing Group (London, UK) and Institute for Healthcare Improvement (Boston, USA), with the support of the the Commonwealth Department of Health and Aged Care (Australia), Safety and Quality Council (Australia), NSW Health (Australia) and Ministry of Health (New Zealand).

For more information contact: quality@bma.org.uk or fax +44 (0) 7383 6869
