Transcranial Doppler sonography during head up tilt suggests preserved central sympathetic activation in familial dysautonomia

M J Hilz, F B Axelrod, U Haertl, C M Brown, B Stemper

Objective: Cerebral autoregulation was assessed by transcranial Doppler sonography in 10 patients with familial dysautonomia and 10 age-matched controls.

Methods: Blood pressure, heart rate, and middle cerebral artery blood flow velocity (CBFV) were simultaneously recorded when supine and during 180 seconds of head up tilt. Cerebrovascular resistance (CVR) was calculated from CBFV and mean blood pressure was adjusted to brain level.

Results: In the controls, mean blood pressure remained stable during tilt, but heart rate increased significantly. In the patients with familial dysautonomia, mean (SD) blood pressure decreased by 15.0 (10.8)% (p < 0.05). Heart rate remained unchanged. In controls, systolic and mean CBFV decreased by 9.1 (4.7)% and 9.4 (7.0)% respectively, while diastolic CBFV remained stable. In the patients, diastolic and mean CBFV decreased continuously by 32.1 (13.9)% and by 14.8 (31.4)%. Supine CVR was 28% higher in patients than in controls and decreased significantly less during head up tilt.

Conclusions: Tilt evokes orthostatic hypotension without compensatory tachycardia in patients with familial dysautonomia owing to decreased peripheral sympathetic innervation. High supine CVR values and relatively preserved CVR during tilt suggest preserved central sympathetic activation in familial dysautonomia, assuring adaptation of cerebrovascular autoregulation to chronic supine hypertension and orthostatic hypotension.

Familial dysautonomia is an autosomal recessive disorder with extensive deficit of sensory, sympathetic, and some parasympathetic neurones. Peripheral sympathetic failure is considered to be the cause of cardiovascular lability. However, impaired cerebrovascular autoregulation might contribute to autonomic dysregulation, with orthostatic hypotension and other disturbance such as cardiac arrhythmias, syncope at rest, and sudden death.

To investigate central autonomic dysfunction in patients with familial dysautonomia, we assessed cerebral vascular perfusion and cerebral autoregulation during passive head up tilt.

METHODS

Ten patients with familial dysautonomia (five women and five men, mean (SD) age 26.9 (9.4) years) and 10 healthy controls (four women and six men, age 25.2 (12.7) years) participated in the study. All the patients with familial dysautonomia fulfilled accepted diagnostic criteria and had the characteristic genetic haplotype. Only patients who were able to discontinue their drug treatment (fluudrocortisone or midodrine) 18 hours before testing participated in the study. Informed consent was obtained according to the declaration of Helsinki.

An 80° head up tilt was initiated after 25 minutes of supine rest. Cerebrovascular and cardiovascular responses were analysed during three minutes of tilt. We monitored heart rate and systolic, diastolic, and mean blood pressure (BPsys, BPdia, BPmean) using left radial artery applanation tonometry with the wrist at heart level, end tidal CO2 (Colin Pilot71, San Antonio, Texas, USA), respiratory frequency using inductance plethysmography (Respiritrace72, Ardsley, New York, USA), and systolic, diastolic, and mean cerebral blood flow velocities (CBFVsys, CBFVdia, CBFVmean) of the left or right middle cerebral artery using transtemporal Doppler sonography (35–55 mm insonation depth, 2 MHz probe; PioneerTM, EME/Nicolet, Madison, Wisconsin, USA).

Cerebrovascular resistance (CVR) was calculated as mean blood pressure adjusted to brain level (BPmean_brain) divided by CBFVmean. We calculated BPmean_brain as the difference between BPmean and the hydrostatic pressure effect (BPhydro) at the level of transcranial insonation, as described elsewhere. All participants were instructed to maintain their regular breathing pattern during the test.

Biosignals were sampled synchronously at 1 kHz and transferred after analogue to digital conversion into a data acquisition and analysis system (HRviewTM, BMTTM, Wakefield, Massachusetts, USA).

Average baseline values were obtained during a 60 second interval that ended 30 seconds before tilting to avoid any bias by activities preceding the tilt. For each second of tilt, variables were determined in relation to baseline values.

Sym pathetic and parasympathetic heart rate modulation was assessed from 256 second epochs at baseline and during tilt, as previously described. Low frequency heart rate oscillations (LF: 0.04–0.15 Hz) are mediated by sympathetic and parasympathetic activity at rest11–12 and predominantly by sympathetic activity during tilt;12 high frequency oscillations (HF: 0.04–0.15 Hz) reflect parasympathetic activity.11–12

From the heart rate tachogram at baseline and during head up tilt we calculated the root mean square successive differences (RMSSD) as a measure of parasympathetic activity,11 and the standard deviation (SD) and coefficient of variation (CV), both reflecting sympathetic and parasympathetic heart rate modulation.11

Statistics

Data are presented as mean (SD). Mean values during the 180 second tilt were compared with baseline values by a two sided...

Abbreviations: BPmean_brain, blood pressure adjusted to brain level; CBFV, cerebral blood flow velocity; CVR, cerebrovascular resistance; HF, high frequency; LF, low frequency; RMSSD, root mean square of successive differences; TCD, transcranial Doppler
to decline, CBFVsys started to recover after 20–30 seconds of tilt significantly reduced (fig 1). While both velocities continued pressure remained stable, with only BPdia increasing (by 14.2 immediately (average increase, 23.9 (8.8)%) (fig 1). Blood controls, but the difference was not statistically significant.

The patients with familial dysautonomia showed impaired peripheral cardiovascular and cerebrovascular responses during tilt. The peripheral sympathetic deficiency was evidenced by postural hypotension without compensatory tachycardia and can be attributed to a reduction in sympathetic neurones in the intermediolateral column and the sympathetic ganglia as well as to an absence of autonomic vascular nerve terminals. However, the intermediate blood pressure recovery after the onset of tilt suggests an incomplete peripheral denervation, allowing for some residual peripheral vasoconstriction (fig 1). The inadequate decrease of RMSSD, SD, and HF power of heart rate oscillations (0.04–0.15 Hz), RMSSD, root mean square of successive differences.

**DISCUSSION**

During tilt, our controls had normal cardiovascular responses, with parasympathetic withdrawal and sympathetic activation as expressed by increased LF power and decreased RMSSD, CV, and HF power of heart rate. Cerebral autoregulation was also normal and assured almost unchanged cerebral blood flow velocities. In both groups, end tidal CO2 changes were minimal and would not explain any changes in cerebral blood flow velocity.

The patients with familial dysautonomia showed impaired peripheral cardiovascular and cerebrovascular responses during tilt. The peripheral sympathetic deficiency was evidenced by postural hypotension without compensatory tachycardia and can be attributed to a reduction in sympathetic neurones in the intermediolateral column and the sympathetic ganglia as well as to an absence of autonomic vascular nerve terminals. However, the intermediate blood pressure recovery after the onset of tilt suggests an incomplete peripheral denervation, allowing for some residual peripheral vasoconstriction (fig 1). The inadequate decrease of RMSSD, SD, and HF power probably reflects additional cardiovascular dysfunction—for example, the baroreflex failure that occurs in familial dysautonomia and impairment of central carotid activation, which has been noted independently of baroreflex function.

In the patients with familial dysautonomia, mean and diastolic cerebral blood flow velocity decreased while systolic velocity increased during tilt. Theoretically, this discrepancy might be the result of a temporary improvement in cardiac performance caused by a reduction in afterload on tilting. In a patient with diabetic autonomic neuropathy, Novak et al observed impaired cerebral autoregulation similar to our findings, with a decrease in mean and diastolic cerebral blood flow velocity and stable systolic velocity during orthostatic hypotension. These investigators attributed the preserved systolic flow to an increase in cardiac contractility during orthostasis. However, such a mechanism should stabilise systolic blood flow immediately on tilt. In our patients, systolic blood flow velocity only returned to baseline values after 20 to 30 seconds of tilt. It is more likely that the decrease in diastolic flow with maintenance of systolic flow during tilting result from a change in downstream perfusion of the small cerebral resistance vessels.

**RESULTS**

Table 1 shows the supine values of the patient and control groups. When supine, heart rate and blood pressure values were higher in the patients than in the controls. CBFV, respiratory frequency, and end tidal CO2 did not differ between the groups. CVR was 28% higher in the patients than in the controls, but the difference was not statistically significant.

Upon tilt, the heart rate of the controls increased immediately (average increase, 23.9 (8.8)%) (fig 1). Blood pressure remained stable, with only BPsys increasing (by 14.2 (28.3)%). Systolic, mean, and diastolic CBFV values decreased slightly but not significantly in controls.

hypotension. Therefore, a passive collapse of excessively dilated vessels during tilt—as suggested by Schondorf et al—does not seem to explain the changes in cerebral vascular resistance and blood flow velocity.

The changes in these variables in our patients are more readily explained by the mechanisms discussed by Grubb et al. These investigators attributed the decrease in diastolic cerebral blood flow velocity with a stable systolic velocity to “paradoxic intracerebral vasoconstriction” during increasing hypotension. Owing to their deficient peripheral sympathetic nervous system, patients with familial dysautonomia cannot maintain peripheral vasoconstriction and blood pressure. However, they seem able to generate a degree of tone in the intracerebral resistance vessels sufficient to counterregulate supine hypertension and prevent syncope despite hypotension. We conclude that there is a discrepancy between the peripheral sympathetic deficiency and a preserved ability to activate central sympathetic or neuropeptide outflow, both maintaining cerebral vessel tone in the face of supine hypertension or orthostatic hypotension.

In the controls, the pronounced vasodilation during head up tilt reflects normal autoregulation involving a reduction in sympathetic nerve activity and a decreased release of vasoconstricting chemical mediators and neuropeptides. In patients with familial dysautonomia, the mechanisms adapting cerebral autoregulation to chronic orthostatic hypotension are unknown but may involve increased central sympathetic outflow or neuropeptide release similar to the mechanisms postulated by Grubb et al for patients with neurally mediated syncope.

Both Schondorf et al and Grubb et al observed a similar decrease in diastolic cerebral blood flow velocity with unchanged systolic velocity during orthostatic hypotension in patients with neurally mediated syncope. Schondorf et al attributed the selective slowing of diastolic velocity with unchanged systolic velocity to a passive collapse of small vessels and a sudden orthostatic fall in systemic blood pressure, the driving force of cerebral perfusion. These investigators assume that neurally mediated syncope results from an excessive dilatation and consequent passive collapse of small vessels occurring when arterial critical closing pressure exceeds venous pressure. Our measurements of cerebral vascular resistance suggest that this mechanism of exaggerated dilatation is unlikely to be operative in the patients with familial dysautonomia. In the supine position, vascular resistance was approximately 28% higher in our patients than in the controls, which assured a similar blood flow velocity despite the supine hypertension in the patients. During head up tilt, cerebral vascular resistance decreased less in the patients than in the controls. These findings indicate that the tone of intracerebral resistance vessels is higher in the patients, not only during supine hypertension but also during progressive orthostatic hypotension.
