Autonomic nervous system testing may not distinguish multiple system atrophy from Parkinson’s disease

D E Riley, T C Chelimsky

Background: Formal laboratory testing of autonomic function is reported to distinguish between patients with Parkinson’s disease and those with multiple system atrophy (MSA), but such studies segregate patients according to clinical criteria that select those with autonomic dysfunction for the MSA category.  

Objective: To characterise the profiles of autonomic disturbances in patients in whom the diagnosis of Parkinson’s disease or MSA was based on criteria other than autonomic dysfunction.  

Methods: 47 patients with parkinsonism and autonomic symptoms who had undergone autonomic testing were identified and their case reports reviewed for non-autonomic features. These patients were classified into three diagnostic groups: Parkinson’s disease (19), MSA (14), and uncertainty (14). The performance of the patients with Parkinson’s disease was compared with that of the MSA patients on five autonomic tests: RR variation on deep breathing, heart rate changes with the Valsalva manoeuvre, tilt table testing, the sudomotor axon reflex test, and thermoregulatory sweat testing.  

Results: None of the tests distinguished one group from the other with any statistical significance, alone or in combination. Parkinson’s disease and MSA patients showed similar patterns of autonomic dysfunction on formal testing of cardiac sympathetic and parasympathetic, vasomotor, and central and peripheral sudomotor functions.  

Conclusions: This study supports the clinical observation that Parkinson’s disease is often indistinguishable from MSA when it involves the autonomic nervous system. The clinical combination of parkinsonism and dysautonomia is as likely to be caused by Parkinson’s disease as by MSA. Current clinical criteria for Parkinson’s disease and MSA that direct patients with dysautonomia into the MSA group may be inappropriate.
day of testing. All patients underwent four tests, three of cardiovascular autonomic function (cardiac response to deep breathing, cardiovascular response to the Valsalva manoeuvre, and cardiovascular response to upright tilt) and one of sudomotor function (the axon reflex sweating test). Some patients underwent an additional test of sudomotor function, the thermoregulatory sweat test, if diagnostic questions remained and underwent an additional test of sudomotor function, the axon reflex sweating test. Some patients and cardiovascular response to upright tilt) and one of sudomotor function (the axon reflex sweating test). However, upright tilt increased his blood pressure by 50/26 mm Hg, and thermoregulatory sweat testing was not done. When the thermoregulatory sweat test was undertaken, it was abnormal in all tested patients from both

Tilt table testing was done at 90° from horizontal for 10 to 20 minutes, after 20 minutes in the supine position.

The axon reflex test used 10% acetylcholine iontophoresed in five sites (dorsum of both feet, lateral calf, dorsum of the hand, and forearm) using 2 mA direct current for five minutes. Sweat output was recorded for this time and for an additional five minutes using a thermal conductivity based device.

The thermoregulatory sweat test employed an environment of 50% humidity and 50°C (skin at 40°C) for 30 minutes, or when core temperature had increased by more than 1.5°C. The presence of gait ataxia (n = 2), or mixed features of Parkinson’s disease and MSA (three Parkinson’s disease features and four MSA features) (n = 1). Fourteen patients were diagnosed with MSA, with a mean (SD) age of 66 (6.0) years and disease duration of 5.7 (3.8) years. Nineteen patients with Parkinson’s disease had a mean age of 69 (9.9) years and a disease duration of 5.8 (4.0) years.

Abnormal results on individual tests occurred in a majority of patients in each group (table 2). Only one patient (who had Parkinson’s disease) had no classic autonomic abnormalities (that is, normal deep breathing and Valsalva manoeuvre, no orthostatic hypotension or tachycardia on tilt, and a normal axon reflex test). However, upright tilt increased his blood pressure by 50/26 mm Hg, and thermoregulatory sweat testing was not done. When the thermoregulatory sweat test was undertaken, it was abnormal in all tested patients from both

Statistical analysis

The review of the patients’ clinical records and patient group assignments were completed independently of and before the statistical analysis of laboratory results. Autonomic test results were judged normal or abnormal by comparison with normal value ranges for comparable demographic categories. Data were compared across the two patient groups using a two tailed Student t test with expected probability (p) value for significance corrected to 0.1 by the Bonferroni method.

RESULTS

We reviewed 47 patients’ records. Fourteen patients were given an uncertain diagnosis owing to insufficient clinical data to qualify for either Parkinson’s disease or MSA (n = 11), sufficient features to warrant a diagnosis of Parkinson’s disease in the presence of gait ataxia (n = 2), or mixed features of Parkinson’s disease and MSA (three Parkinson’s disease features and four MSA features) (n = 1). Fourteen patients were diagnosed with MSA, with a mean (SD) age of 66 (6.0) years and disease duration of 5.7 (3.8) years. Nineteen patients with Parkinson’s disease had a mean age of 69 (9.9) years and a disease duration of 5.8 (4.0) years.

Abnormal results on individual tests occurred in a majority of patients in each group (table 2). groups. Figure 1 shows typical findings. One patient in each group had a classic myelopathic pattern, at the mid-thoracic level. We found an abnormal axon reflex sweat test in the same proportion of patients in both groups.

No individual test distinguished the two groups of patients, either by the frequency or by the magnitude of abnormal results (table 2). Pairing the two tests showing the greatest disparity between the two groups (the trend toward an abnormal response to deep breathing with a normal response to the Valsalva manoeuvre in the MSA group, table 2) did not prove statistically significant in distinguishing the two groups.

Of note in the MSA group, there appeared to be a discrepancy between vital sign changes on tilt table testing and symptoms suggestive of hypotension, some patients being more symptomatic than expected and others less. None of the four MSA patients with a systolic blood pressure fall of $>50$ mm Hg had no symptoms, while three of the four patients with a blood pressure fall of $<30$ mm Hg had orthostatic symptoms. In summary, nine of 11 MSA patients had symptoms that did not correlate with expectations based on vital sign changes, compared with six of 14 Parkinson's disease patients. The difference constituted only a trend towards statistical significance ($p = 0.05$).

Some patients were unable to complete one or more segments of the test battery. Inability to perform the Valsalva manoeuvre occurred more often in the MSA group ($p < 0.01$).

**DISCUSSION**

We sought to study autonomic function in Parkinson's disease and MSA patients after attempted elimination of selection bias based upon the degree of symptomatic dysautonomia. We studied a group of parkinsonian patients with dysautonomia and segregated them according to those clinical features (other than autonomic dysfunction) that had previously been...
shown in clinicopathological studies to be more characteristic of either Parkinson's disease or MSA (table 1). We were unable to find any distinguishing characteristics in the profiles of their deficits on the autonomic test battery employed (table 2). Our results indicate that formal testing of autonomic function cannot distinguish between patients with Parkinson's disease and MSA who have autonomic symptoms when the presence of such symptoms is not included in the diagnostic criteria. We cannot exclude the possibility that this finding resulted from an inadequate sample size. However, our results support anecdotal observations that the pattern of autonomic dysfunction in Parkinson's disease mimics that of MSA, and that autonomic studies cannot distinguish the two. We do not know how widespread is the arbitrary designation of the combination of parkinsonism and dysautonomia as MSA in clinical practice. However, two reports on autonomic function in Parkinson's disease and MSA where diagnosis was based on postmortem confirmation were instructive. In one, a majority of the patients with Parkinson's disease and clinical dysautonomia was misdiagnosed as having MSA. In the other, none of 10 MSA patients (from a cohort of 33 patients) who were clinically misdiagnosed as Parkinson's disease had autonomic problems at disease onset, while 46% of the correctly diagnosed MSA patients did. Interestingly, in the latter study a retrospective review found that 76% of the 135 patients with Parkinson's disease had some degree of autonomic dysfunction during life, despite the observation by the investigators that the case records of patients correctly diagnosed premortem with MSA showed more diligent searches for autonomic symptoms than those of Parkinson's disease patients. This figure is comparable to the 74% frequency of autonomic dysfunction in 203 pathologically proven cases of MSA in Wenning et al's review. Our results cannot be used as epidemiological data describing the frequency of autonomic disturbances in Parkinson's disease or MSA, as all the patients were selected for laboratory study on the basis of autonomic symptoms. As the prevalence of Parkinson's disease appears to be many times that of MSA, the relatively equal proportions of our two patient groups support the notion that autonomic disturbances are indeed more common in MSA than in Parkinson's disease. Thus an absence of dysautonomia in a patient with parkinsonism suggests the diagnosis of Parkinson's disease. However, our study also indicates that, in an individual patient, the combination of parkinsonism and dysautonomia is at least as likely to result from Parkinson's disease as MSA. Current clinical diagnostic criteria allow for considerable overlap between Parkinson's disease and MSA. One consequence is that many MSA patients appear indistinguishable from those with Parkinson's disease, even up to death. Correspondingly, patients with Parkinson's disease may present a clinical picture identical to that of MSA. Confusion arises chiefly because both diseases can lead to a combination of parkinsonism and dysautonomia. A means of distinguishing between the two conditions other than by existing clinical criteria is needed, as segregation of patients according to the presence or absence of dysautonomia appears to be inadequate and inappropriate.

Finally, some of our laboratory observations warrant further comment. The universal abnormality of thermoregulatory sweat test in both patient groups suggests that this test may be the most sensitive one for autonomic involvement in both Parkinson's disease and MSA, but the number of patients tested was small. The patterns of anhidrosis were similar in the two groups (fig 1), ranging from the expected “central pattern” which was most common, to segmental, and myelopathic, shown by one patient in each group. This wide spectrum of anhidrotic patterns implies that initial involvement and progression of autonomic system cellular loss varies considerably. The comparable abnormality of axon reflex testing suggests ganglionic or postganglionic involvement in the majority of patients in both groups. Rajput and Rozdilsky attributed dysautonomia in Parkinson's disease to neuronal loss and Lewy body formation in sympathetic ganglia, while Bannister and Oppenheimer correlated dysautonomia in MSA with degeneration of the intermediolateral cell column of the spinal cord. However, our results are consistent with reports of impaired postganglionic sympathetic function demonstrated by impaired sweat axon reflexes in MSA patients. The seemingly paradoxical relation between symptoms and signs that we found on tilt table testing, particularly striking in the MSA group, deserves further exploration in the future. Other investigators have noted a lack of symptoms in MSA patients with orthostatic hypotension. MSA patients may be quite symptomatic early in their disease course, but may lose the ability to develop orthostatic symptoms when vasomotor failure is advanced.
