Failure to detect *Chlamydia pneumoniae* DNA in cerebral aneurysmal sac tissue with two different polymerase chain reaction methods

S Cagli, N Oktar, T Dalbasti, S Erensoy, N Özdamar, S Göksel, A Sayiner, A Bilgiç

**Objective:** *Chlamydia pneumoniae* (*C. pneumoniae*) is a common cause of a usually mild, community-acquired pneumonia. This organism, however, can spread from the respiratory tract into other parts of the body and has been detected in up to 70% of atheromatous lesions in blood vessels. Although the exact mechanism of the *C. pneumoniae* contribution to the pathogenesis of atherosclerosis remains unknown, prophylactic antibiotic trials are planned for people at high risk for coronary disease.

**Method:** In this study the authors aimed to investigate *C. pneumoniae* DNA content in the cerebral aneurysmal sac tissue with the aid of polymerase chain reaction (PCR) method. *C. pneumoniae* DNA was searched in 13 surgically clipped and removed aneurysmal sac tissue and in two tumour (an ependymoma of the fourth ventricle and a craniopharingioma) samples by touchdown enzyme time release PCR (TETR PCR) targeting 16S rRNA gene and by nested PCR targeting ompA gene.

**Results:** Both PCR methods were sensitive to detect in *C. pneumoniae* 4×10^-4^ genomes. *C. pneumoniae* DNA was not detected in any of the 17 sample tissues of these patients.

**Conclusion:** The contribution of *C. pneumoniae* in the development of intracranial aneurysms cannot be excluded despite the results of this study. Further studies on the possible role of *C. pneumoniae* or any other micro-organisms in the pathogenesis of aneurysms should be performed.
at 94°C for 45 seconds, annealing beginning at 64°C and ending at 52°C for one minute. The annealing temperature was lowered 10°C every four cycles until 52°C and this temperature was kept until the end of the cycling process.

CP1-CP2 primers with nested pair CPC-CPD were used for the ompA nested PCR. The first round of amplification used 1.5 mM MgCl₂, 0.4 µM of each primer and 20 µl of the extracted DNA. Cycling consisted of nine minutes at 95°C for Taq polymerase activation, 20 cycles of one minute at 94°C, one minute at 65°C (temperature was decreased 0.5°C for each cycle) and one minute at 72°C. The PCR products amplified by the outer primer pair were diluted 1:5 and 5 µl was added to a new PCR mixture containing 1 µM of each primer and 3 mM of MgCl₂. Cycling protocol entailed nine minutes at 95°C for Taq polymerase activation, 30 cycles of one minute at 94°C, one minute at 50°C and one minute at 72°C.

Detection of the human β globin gene
For extraction and PCR inhibition control, a fragment of the human β globin gene was amplified as previously described. All amplification products were analysed by agarose gel electrophoresis and ethidium bromide staining. The expected amplicon sizes were 197bp for TETR PCR, 333bp for ompA outer primer pair, 207bp for ompA inner primer pair and 536 bp for the human β globin gene.

RESULTS
Two different PCR assays were performed to detect C pneumoniae DNA. Both TETR PCR and ompA nested PCR was sensitive to detect 10⁻³ colony forming units. All samples were negative for C pneumoniae DNA (fig 1 and 2). A 536bp fragment of the human β globin gene was detected in all of the samples except one (fig 3).

DISCUSSION
The term “mycotic aneurysm” was first used by Osler in 1885. Subsequently Stengel and Wollerth (1923) reported 217 cases, including their own, of aneurysms developing during bacterial infections. Among these 42 cases had intracranial aneurysms, and since that time at least 30 cases of mycotic aneurysms have been described.
aneurysms have been reported. A review of 1126 cases of intracranial aneurysms in 1939 showed an incidence of 6% mycotic aneurysms. After the introduction of antibiotic treatment of subacute bacterial endocarditis, bacterial cerebral aneurysms have become quite rare. As Yasargil stated “...A more likely error in present-day diagnosis is the failure to consider an aneurysm to be of bacterial embolic origin...” Before the antibiotic era, cerebral aneurysms secondary to infected emboli from the vegetations of endocarditis were not uncommon.

At the beginning of the past century, mycotic aneurysms were thought to account for about one quarter of intracranial aneurysms. The term “arteriosclerotic aneurysm” is used to describe fusiform dilatation of a cerebral vessel in which the wall has undergone atheromatous degeneration. The first comprehensive discussion of this entity was by Dandy in 1944, who encountered 11 cases of elongated and tortuous vascular arteries in the course of posterior fossa procedures. Such serpentine dilatation of the vertebral basilar or internal carotid arteries is a frequent occurrence in patients with severe atherosclerosis. These lesions are usually classified as atherosclerotic aneurysms, although they are not necessarily associated with senile ectasia or atherosclerosis of the vessel, for example, Marfan syndrome, megalodolichobasilaris or idiopathic median necrosis. Atherosclerotic aneurysms accounted for about 50% of the lesions in older statistics and are found in 8% to 16% of Housepian and Pool (1958) and Jellinger’s (1979) series. Ohara et al (1979) distinguished two types of arteriosclerotic aneurysms. One is the type where the trunk arteries, such as the basilar artery, themselves, swell to a fusiform shape (Fusiform aneurysm). The other is the type where a saccular aneurysm arises having no relation to the arterial forks with considerable sclerosis of the parental artery. In Suzuki’s series (1979) eleven of 1116 aneurysm cases (1%) had saccular aneurysms.

C pneumoniae has been associated with atherosclerotic cardiovascular disease by both seroepidemiological studies and direct detection of the organism in atherosclerotic plaque by electron microscopy, immunocytochemistry, and PCR. The role of inflammatory reactions in the pathogenesis of atherosclerosis is widely accepted. Recently, an increasing body of evidence has linked infections to atherosclerosis. It is hypothesised that infections could interact with other risk factors of vascular disease, increasing the endothelial damage and the production of atherosclerotic plaques. Several different infectious agents have been related to the atherosclerosis genesis: mainly herpesvirus, Helicobacter pylori, and C pneumoniae. Several lines of evidence strongly link C pneumoniae to atherosclerosis. Consequently, several studies evaluating the effectiveness of antibiotic treatment in the reduction of cardiac ischaemic events in patients with C pneumoniae seropositivity have been performed.

On the other hand several reports show lack of association between seropositivity to C pneumoniae and carotid atherosclerosis and even C pneumoniae antibodies and high lipoprotein α levels do not predict ischaemic cerebral infarctions. In contrast with previous published papers, Nobel et al could not confirm an association of C Pneumoniae infection with an acute coronary event. Gibbs et al research showed that the presence of the infectious organism has little detectable impact on plaque instability when measured by clinically significant markers. This raises important questions for the rationale of antibiotic therapy in atherosclerosis. The validity of the hypothesis that infection contributes to atherosclerosis has not been definitively established, although the evidence is becoming compelling, with
several interesting studies presented at the 2001 ACC meeting (S E Epstein, 50th annual scientific session of the American College of Cardiology, 19 March 2001). Evidence is also accumulating that autoimmune responses, perhaps triggered by infection, may be one of the mechanisms contributing to atherosclerosis. The concepts are intriguing and will undoubtedly serve as the focus of many investigative studies presented at future meetings (50th annual scientific session of the American College of Cardiology). In the study of Vink et al the prevalences of C pneumoniae at multiple locations in the arterial system within the same person were observed as highest in the abdominal aorta (67%), internal and common iliac arteries (41%), and coronary arteries (33%). The lowest prevalences were observed in the radial (0%) and cerebral (2%) arteries. C pneumoniae was mostly observed at locations that are related to clinically relevant features. Within the patient group, the distribution of C pneumoniae is associated with the distribution of atherosclerosis. The role of the micro-organism in atherosclerotic disease remains to be elucidated. This study and our results with cerebral aneurysms show at least the possible role of C pneumoniae in the patogenesis of the cerebral aneurysms.

In this study, negative results of PCR may be discussed (or questioned) for the presence of PCR inhibitors in the samples or the inefficiency of the PCR. For the assessment of these factors, fragment of human β globin gene was investigated in every sample as an endogenous control. The sensitivity of the PCR methods was determined with positive controls of C pneumoniae culture samples with a known genome. All the samples were found to be positive for β globin gene indicating the absence of PCR inhibitors. Performed TETR PCR and ompA PCR methods were found to be as sensitive to detect 4x10^4 genomes per reaction. We cannot exclude the contribution of C pneumoniae in development of intracranial aneurysms despite the result of this study. Further studies on the possible role of C pneumoniae or any other micro-organisms (such as H pylori, citomegalovirus, autoantibodies against “heat shock” proteins, hepatitis A virus, herpes simplex virus 1 and 2 (HSV-1,-2), Perphyromonas gingivalis, et al) in the pathogenesis of aneurysms should be performed.

Neutralising antibodies to interferon β during the treatment of multiple sclerosis

Giovannoni and colleagues are to be commended for their detailed analysis of the impact of neutralising antibodies (NAB) to interferon β (IFNβ) during the treatment of multiple sclerosis. In general agreement with many of their statements and conclusions, but a few points should be discussed in a wider context.

In the European study of IFNβ-1b in secondary progressive multiple sclerosis (SPMS), the proportion of treated patients who have been NAB positive and subsequently revert back to being NAB negative is about 40% after a treatment duration of up to three years (with the evidence that patients with higher titres revert less frequently). Moreover, in the study by Rice et al., the percentage is close to 80% after a mean treatment duration of more than eight years.

In our opinion, these data suggest that the clinical impact of neutralising antibodies to IFNβ during the treatment of multiple sclerosis may be more limited and more transient than suggested in the editorial, and that the development of neutralising antibodies in itself does not provide justification for switching treatments or for considering aggressive strategies to reduce or reverse the development of neutralising antibodies. Given the current rather uncertain knowledge concerning the impact of neutralising antibodies, we advocate that treatment decisions should be based on clinical grounds rather than on neutralising antibody titres.

Neutralising antibodies to interferon β

I read the editorial by Dr G Giovannoni and colleagues’ with great interest. I have, however, to report a minor error concerning the list of the recipients of the Rebif reported in their table 1. In the table the authors reported the following recipients: mannitol, HSA, sodium acetate, acetic acid, sodium chloride. Actually, as you can check in the summary of product characteristics published from EMEA (www.emea.eu.int) on 29 March 1999, in the list of excipients sodium chloride is absent, whereas sodium hydroxide is present.

Authors’ reply
We would like to thank Dr Ortenzi for pointing out our transcription error in relation to the recipients of Rebif® in table 1 of our editorial.

We agree with Polman and colleagues that recent comparisons show that the more immunogenic higher dose interferon β (IFNβ) preparations are more efficacious than the lower dose less immunogenic preparations over 24 months and six months’ periods of observation. However, as discussed in our editorial, the development of neutralising antibodies and their effects on the clinical efficacy of IFNβ are delayed. In the PRISMS study the effect of neutralising antibodies on clinical efficacy only became apparent after years 3–4. In the pivotal IFNβ-1b study an effect on relapse rate was only observed in the 19–24 and 25–30 month epochs. Hence we would argue that these comparative studies are simply too short, and in the case of the INCOMIN trial underpowered (n = 188), to demonstrate an effect of neutralising antibodies on clinical efficacy. It is therefore impossible to extrapolate the significant short term differences observed in these studies beyond the periods of observation reported.

Because of regression to mean and the well documented tendency for the relapse rate to decrease with disease duration, it is not possible to draw any meaningful conclusions from a comparison of the relapse rate in years 1–2 and years 3–4 from the PRISMS extension study. In addition to the impact of neutralising antibodies on relapse rate, the PRISMS extension study clearly shows—using the more objective T2 lesion volume or burden of disease—that the average annualised increase in lesion volume over four years in the neutralising antibody positive (NAB+) patients is similar to the increase in the annualised lesion volume in the placebo treated patients in the first two years of the study (NAB+ 4.4% vs placebo 5.45%). Similarly, in the IFNβ-1b study the annualised relapse rate of NAB+ patients is identical to patients on placebo (1.08 vs 1.06). In the IFNβ-1a (Avonex®) trial, the impact of neutralising antibodies was limited to MRI outcomes. The failure of neutralising antibodies to have an effect on disease progression and relapse rate in this study probably reflects the size and duration of follow up, as the study was terminated prematurely. It is these data from the pivotal relapsing multiple sclerosis clinical
trials, and other studies on in vivo markers of IFNβ activity discussed in our editorial, that we use to support our statement that “interferon β has little if any clinical and MRI efficacy in the presence of neutralising antibodies.”

Data on the impact of neutralising antibodies in secondary progressive multiple sclerosis (SPMS) trials is less clear. This is to be expected, however, as the efficacy of IFNβ on disease progression—the primary outcome measure in SPMS trials—is limited and hence it would be difficult to demonstrate a significant impact on neutralising antibodies on the primary outcome measure when the actual therapeutic intervention itself is only marginally effective.” It would be very surprising if neutralising antibodies had a significant impact on disease progression, as none of the trials is powered to detect an effect of neutralising antibodies on this outcome. For example, in the European SPMS study, 100/360 (28%) of IFNβ-1b treated patients become NAB+ (titre > 20) over the course of the trial. In a conservative approach, by applying the results from the trial,10 and assuming that NAB+ patients behave as if they are on placebo and NAB− patients behave like the historical IFNβ-1b treated cohort, one would expect 49.8% of the 100 NAB+ patients to progress over three years, compared with 38.9% of the 260 NAB− patients. At the same level of significance (0.029) from the original study, it would only have a 35% chance of detecting a significant difference between NAB+ and NAB− patients (Fishers exact test). Compare this to a power of 80% used in the design of the original study. This power calculation is an overestimate as it ignores the therapeutic effect observed before the development of neutralising antibodies, as evidenced in this study,9 which if taken into account would seem reasonable if there are no carryover therapeutic effects of IFNβ-1b treatment from the NAB− to NAB+ phase and if the follow up in the NAB+ phase is of sufficient duration to account for the delayed effects (24 to 48 months) of neutralising antibodies on clinical efficacy. In this study the mean follow up in the NAB+ phase would be on average too short (less than 24 months) for one to be confident of excluding a delayed effect of neutralising antibodies on disease progression. Despite the lack of power of these subanalyses, they produce some surprising results. In the cross sectional study there was a trend toward greater disease activity in the NAB+ group in the third year, and a significant percentage T2 volume change from baseline to year 1, year 2, and the last visit; in the underpowered and potentially flawed longitudinal analysis there was no indication of an attenuation of treatment effects on disability progression but, surprisingly considering the lower relapse rate in secondary progressive multiple sclerosis, there was a robust effect on relapse rate.

Another way of interpreting the European SPMS NAB data as presented by Polman and colleagues is that the much higher dose of IFNβ-1b (875 μg/week) given in that study, in comparison with the lower licensed doses of IFNβ-1a (30–132 μg/week), acted to quench some of the neutralising activity of the antibodies. Similarly, the higher doses may be responsible for inducing high dose tolerance in a subset of the patients. These phenomena are well observed with other biologicals in which the read-outs are more objective than in multiple sclerosis—for example, coagulation in anti-factor VIII and glucose levels in anti-insulin antibody positive patients.

Polman and colleagues have misinterpreted our recommendations. We do not recommend routine screening of neutralising antibodies at present, nor the switching of treatments in NAB+ patients unless clinically justified, nor aggressive strategies to reduce or reverse the development of neutralising antibodies. We simply state that further research is necessary to assess whether these strategies are appropriate. Polman and colleagues’ concluding statement that treatment decisions should be based on clinical grounds rather than on neutralising antibody titres is entirely in keeping with our recommendations.

We disagree with Polman and colleagues’ statement that “the clinical impact of neutralising antibodies to interferon β during treatment of multiple sclerosis may be more limited and niefture suggested in the editorial.” Short to intermediate term data (< 4 years) from the relapsing multiple sclerosis studies discussed above10 do not support this claim, and long term clinical data (> 4 years) on the effects of transient neutralising antibodies on the therapeutic efficacy of IFNβ-1b do not exist to support the latter half of their claim. In addition, evidence in our statement is yet to support whether or not the phenomenon of transient high titre neutralising antibodies occurs to a similar degree in patients treated with IFNβ-1a; therefore the latter half of their statement, if true, may not be applicable to patients treated with IFNβ-1a.

In conclusion, clinicians cannot ignore the issue of neutralising antibodies, particularly in view of the evidence from other fields of medicine in which neutralising antibodies reduce or inhibit the efficacy of a wide range of biologicals, including type I interferons. Why should interferon treatment in multiple sclerosis be any different?

A 1908 systematic review of the laterality of hysterical hemiplegia

Since the publication of our systematic review of the laterality of functional or medically unexplained weakness and sensory disturbance (1965–2000) we have come across a further study from 1908 with a similar aim.

Ernest Jones, later an eminent figure in the psychoanalytic movement, published his paper in French while working as an assistant physician at the London School of Medicine. He reported on the cumulative analysis of 277 cases of hysterical hemiplegia described by 146 authors in 164 articles published between 1880 and 1908. Most of this material is in French and German and includes cases mentioned in doctoral theses and books.

There was no excess of left sided hemiplegia compared with right in hysteria in his analysis—54% had paralysis on the right side and 46% on the left. This was contrary to the prevailing opinion of the time11 and also disagrees with another less systematic review of older studies (covering 100 subjects, 13 publications and 6 authors between 1885–1937).12 Jones’ conclusions—that the laterality of hysterical hemiplegia has no diagnostic value—were the same as ours. His study has not been cited for at least 40 years (and probably much longer even than that). It has been neglected, like many other negative studies before and since, but it deserves recognition on this subject.

Resolution of psychiatric symptoms secondary to herpes simplex encephalitis

We read with interest the editorial by Kennedy et al.,1 detailing the short-term treatment of herpes simplex encephalitis (HSE). We agree with the authors that we cannot overemphasise the seriousness of the neuropsychiatric symptoms that a number of these patients display in the long term.

We report a 55 year old woman who was diagnosed with HSE; diagnosis was confirmed with a positive PCR test for herpes simplex in the CSF and acyclovir was started the following day after presentation. After a few weeks the patient’s recovery was almost complete and she was discharged home. Six months later, there was an abrupt change when the patient developed insomnia and would sit up all night watching children's videos; she also became hostile and confused. She was admitted to a psychiatric unit where she continued to be confused and agitated with episodes of extreme behaviour such as undressing or trying to attack staff.

MRI showed appearances consistent with severe left hemiparesis and gliosis in the right temporal lobe with evidence of gliosis in the frontal and temporal lobes consistent with previous HSE. It was surprising that the EEG tracing was normal with no focal or epileptiform features. The patient remained in the psychiatric unit for seven months during which time she failed to respond to different antipsychotic medications and she was heavily sedated. The nursing staff reported that the patient was generally confused but there were distinctive episodes when the patient would stare and then display abusive and disruptive behaviour for periods of up to an hour once or twice a day. A sleep study was started and when the patient reached a dose of 400 mg twice daily these episodes ceased completely and the patient’s behaviour showed dramatic improvement. She continued to have mild cognitive impairment affecting mainly short-term memory.

Psychiatric problems after HSE are not uncommon; Hokkanen et al.1 found that psychiatric problems are the major cause of long-term disability in these patients.3 Despite the fact that clinical relapse of HSE is well documented,2 cognitive and psychiatric problems are usually already in place in the acute stage and further deterioration or relapse is uncommon.2 In our case the comparatively long period between recovery and onset of behavioural and psychiatric symptoms seemed to cast doubt about the association with the HSE and uncertainty regarding the appropriate treatment.

Vallini et al.1 reported successful treatment of a HSE patient presenting with severe emotional liability and explosive emotional outbursts.1 The patient responded to carbamazepine, which was started after his EEG showed seizure activity detected in temporal structures. Despite the absence of any EEG abnormalities in our case, it showed a similar favourable response to carbamazepine. We feel that any patient with intractable behavioural or psychiatric symptoms after HSE should have a therapeutic trial of carbamazepine, even in the absence of any clinical or neuropathological evidence of seizure activity.

Authors’ reply

Gaber and Eshiett report an interesting case of carbamazepine responsive neuropsychiatric syndrome following herpes simplex encephalitis (HSE). Neuropsychiatric symptoms after HSE are well recognised.1 The left temporal and limbic lesions in HSE are particularly likely to cause behavioural and psychiatric symptoms. Retrospective studies have previously implicated HSE in the delayed syndromes of violent and psychotic behaviour2 and depression.1 However, psychiatric disorders are also common after non-herpes virus encephalitis.1,3 Hunter and Hunter2 described a patient with episodic psychiatric symptoms after serious, acute, neurological illness in early childhood.2 Med Child Neonatal Child Neurol 1993;53 (suppl 68):11–17.

We agree with the authors that we cannot overemphasise the seriousness of the neuropsychiatric symptoms that a number of these patients display in the long term. Despite the absence of any EEG abnormalities in our case, it showed a similar favourable response to carbamazepine. We feel that any patient with intractable behavioural or psychiatric symptoms after HSE should have a therapeutic trial of carbamazepine, even in the absence of any clinical or neuropathological evidence of seizure activity.

Radiofrequency neurotomy

In reading the study by Govind and colleagues,1 in which they report the findings of an unblinded, uncontrolled, non-randomised trial of radiofrequency neurotomy for the treatment of third-occipital headache, we are surprised that the authors advocate this therapy.

The last statement of the abstract is: “No other form of treatment has been validated for this common form of headache”. This implies that Govind et al believe they have validated radiofrequency neurotomy for the treatment of third-occipital headache. Presumably they are prepared, given the apparently impressive numbers of responders, to forego the usual practice of placebo controlled trials. We do not understand how the authors can expect this treatment to be realistically adopted in clinical practice with no attempt to validate it the way treatments are meant to be validated, through randomised, placebo controlled trials. The statement in their final paragraph that “some practitioners may be averse to implementing a treatment that requires repetition” could perhaps more appropriately state that “some practitioners may be averse to implementing a treatment that remains unvalidated”.

The authors state that one reason they did not do a placebo controlled study is that a previous study has already validated this technique in other patients.2 That a single trial of radiofrequency neurotomy in 24 so-called “whiplash patients” is sufficient basis for the current authors to abandon validation with a placebo method seems absurd, especially when closer inspection of that trial lays it in a less positive light.2 We do not accept an argument that it was impossible to blind these subjects. It would be entirely reasonable to see just how often a placebo procedure does indeed...
“fool” the patient. Govind et al seem to have already decided that this is not possible, a convenient assumption.

Further, we are concerned that Govind et al state categorically that “among patients with whiplash injuries, third occipital headache is common”. The study group from which they determine this prevalence has been reviewed elsewhere, and is wholly inappropriate for a prevalence estimate, being best described as an unusual, highly select, and heterogeneous group of subjects. It is of note that, in regard to validated therapies for whiplash patients, the current study would have been rejected by the criteria of the Quebec Task Force on Whiplash Associated Disorders. We suggest that an invasive procedure should not be advocated until it has been subjected to proper study. Fortunately, we are aware that others are undertaking a properly controlled trial of this form of therapy.

Authors’ reply

Our study reported an audit of outcomes for a treatment of a condition for which there is no other treatment available. It showed what proportion of patients obtained complete relief of pain, and for how long. Readers who wish to adopt this treatment for their patients can do so. If not, they should explain to their patients that they, personally, cannot offer them any treatment that is known to work; but they should not claim that there is no treatment. Our study shows that there is an option.

A placebo controlled trial would not prove that this treatment does not work. The outcomes should be the same as the benchmark established by our study, unless the operators perform the procedure poorly. A placebo controlled study could only show that all or part of the outcome is attributable to non-specific effects.

We consider this to be an unlikely outcome for we have never encountered in any of our own studies, nor in the literature, results showing that 86% of patients obtain complete relief of spinal pain following a sham procedure. Radiofrequency neurotomy has been shown to be associated with placebo responses in only a small proportion of patients, and for a limited duration. They claim that responses to third occipital neurotomy is only a conjure. In principle it is worthy of testing, but in practice it cannot be tested.

The precepts of informed consent require that participants in a randomised controlled be informed of all the consequences and potential complications of a procedure. Numbness in the territory of the third occipital is an unavoidable side effect of third occipital neurotomy is a sign that the target nerve has been coagulated. It is an essential requirement for the procedure to work. The numbness lasts as long as the pain relief lasts. In a double blind trial this side effect cannot be masked. Therefore, patients who underwent a sham procedure would automatically know that they did not have the real treatment. Thereby the patients would be unblinded. Any placebo controlled trial which suffered unblinding would be fatally flawed and, therefore, unacceptable.

Any study that used a control short of a sham procedure would also be flawed, and would not escape criticism. Panduits would argue that patients would recognise that simply blocking the nerve, or simply inserting the electrode without mimicking the two hour procedure assiduously, is an obvious sham, and that any patient so treated would exhibit a nocebo effect.

For these reasons we did not venture to conduct a placebo controlled trial. If Dr Kwan and Dr Friel can show that a sham procedure on the third occipital nerve succeeds in achieving complete relief of pain in 86% of their patients we will gladly convert to their sham procedure.

We recognise it as a pity that our study would not be accepted by systematic reviews; but that is a problem for those who rely on reviews as the only source of evidence. In that regard we stand in good company. Were we to rely only on systematic reviews, radiofrequency neurotomy for trigeminal neuralgia would not be an accepted treatment; nor would we be allowed to perform appendicectomies.

While others are satisfied to deny care to patients while they engage in purist debates about levels of evidence, we are rewarded with patients grateful for the relief that they obtain, and who report: “you must repeat the procedure because I am never going back to suffering headaches again”. If someone devises a better treatment for third occipital headache, we will adopt it. In the meantime we feel it would be dishonest of us to tell our patients there is nothing we can do for you.

CORRECTIONS

In the neurological picture of the June issue (Komotor JR, Clatterbuck RE. Cocidiodymomycosis of the brain, mimicking en plaque meningioma. J Neurol Neurosurg Psychiatry 2003;74:806) the initials of the first author were reversed; his name should read as Komotar BJ.

The ordering of the authors in the letter by Soragna D, Tupler R, Ratti et al in the June issue (An Italian family affected by Nasuh-Hakola disease with a novel genetic mutation in the TREM2 gene. J Neurol Neurosurg Psychiatry 2003;74:825–6) is incorrect, it should be as follows: D Soragna, L Papi, MT Ratti, R Sestini, R Tupler, L Montalbetti.

The ordering of the authors in the letter by De Tiège, Laureys, Goldman, et al in the July issue (Regional cerebral glucose metabolism in akinetic catatonia and after remission. J Neurol Neurosurg Psychiatry 2003;74:1003–4) is incorrect, it should read as follows: X De Tiège, JC Bier, L Massat, S Laureys, F Lotstra, J Berré, J Mendlewicz, S Goldman.

In the June issue of JNNP fig 1 of the paper by Caygl S, Oktar N, Dalbasti T, et al (Failure to detect Chlamydia pneumoniae DNA in cerebral aneurysm sac tissue with two different polymerase chain reaction methods. J Neurol Neurosurg Psychiatry 2003;74:756–9) was incorrect. The following figure is the correct image that should have been published.

Figure 1 C pneumoniae TETR PCR of clinical samples. Lanes 1 to 3, 5 to 7 clinical samples. Lanes 4 and 8 negative control (water). Lanes 9 and 11 positive control (C pneumoniae 4×10⁴ and 4×10² CFU). Lane 10 water. Lane 12 DNA molecular weight marker (XIV, 100 bp ladder, Roche Diagnostics). (Correction to J Neurol Neurosurg Psychiatry 2003;74:756–9.)
