Normal jugular bulb oxygen saturation

A Chieregato, F Calzolari, G Trasforini, L Targa, N Latronico

Background: Normal values of the jugular bulb oxygen saturation were obtained in 1942 and in 1963. Correct catheter positioning was not confirmed radiologically.

Objectives: To replicate the measurements during angiographic catheterisation of the jugular bulb.

Methods: Oxygen saturation in the jugular bulb (SjO2), inferior petrosal sinus (SipsO2), and internal jugular vein was bilaterally measured in 12 patients with Cushing’s syndrome undergoing selective bilateral catheterisation of the inferior petrosal sinus. In addition, data from the two old series were reanalysed for comparison.

Results: SjO2 values (44.7%) were significantly lower than in the two old series, particularly concerning the normal lower limit (54.6% and 55.0% respectively). Comparative analysis suggests that contamination with the extracerebral blood of the facial veins and inferior petrosal sinuses was responsible for falsely high SjO2 values in the two old series.

Conclusions: The normal lower SjO2 limit is lower than previously recognised. This may have practical implications for treating severe head trauma patients.

Monitoring of jugular bulb vascular oxygen saturation (SjO2) is currently suggested in patients with severe head trauma as a global measure of the adequacy of the cerebral blood flow (CBF) to brain metabolic requirements. SjO2 in normal volunteers was first obtained by Gibbs et al in 1942,2 then by Datsur et al in 1963.3 In 1945 Gibbs et al also showed that the SjO2 does not differ in simultaneous sampling of both right and left jugular bulbs.4 However, these physiological data were obtained by direct puncture of the jugular veins without radiological confirmation of the needle’s or catheter’s tip position.

Substantial extracerebral contamination with high oxygen saturation values may occur if the blood is withdrawn from the facial vein, joining a few centimetres below the jugular bulb and possibly from the inferior petrosal sinus, joining immediately below the jugular bulb. Contamination may also occur if the catheter is correctly positioned and blood withdrawal is too fast. Therefore, extracerebral blood contamination could have occurred in the two old series, and falsely high oxygen saturation values could have been obtained.

We sought to replicate the SjO2 measurements during angiographic catheterisation of the jugular bulb.

MATERIALS AND METHODS

The study was approved by the local review board, and written informed consent was obtained by the patients. The study was carried out on 12 patients (nine females; median age 39 years, range 25–72) with Cushing’s syndrome, whose aetiology had to be defined. Selective bilateral venous sampling in the inferior petrosal sinus was necessary to distinguish those individuals with microadenoma of the pituitary from some paraendocrine tumours (for example, carcinoids or phaeochromocytoma) that ectopically produce corticotrophin releasing hormone (CRH) or adrenocorticotrophin hormone (ACTH).5 We took advantage of this procedure, which was done using a digital subtraction angiography system, to obtain multiple bilateral samples from: (1) internal jugular veins at the level of the 5th cervical vertebra (midlevel) (SmidjO2); (2) inferior petrosal sinuses (SipsO2); and (3) dome of internal jugular vein bulbs (SjO2). Correct position of the tip of the catheter was meticulously checked under direct angiographic observation with contrast medium injection. Blood was withdrawn slowly (1 ml per minute) and venous blood was analysed for oxygen saturation with a co-oximeter (IL 482, CO-Oximeter, Instrumentation Laboratory, Milan, Italy).

Patients were excluded if they had abnormal arterial oxygen saturation (<97% in room air), anaemia of recent onset (Hb less than 100 g/l in the past 10 days), or haemodynamic instability. Chronic arterial hypertension is associated with an adaptation of CBF, and metabolic coupling is ultimately affected only by severe involvement of the cerebral vascular circulation.1,2 Therefore, stable hypertension was not an exclusion criterion. Conversely, patients with hypertension of recent onset or with poorly controlled hypertension were excluded. Patients were also excluded if they had evidence of acute or chronic diseases affecting the central nervous system (CNS) other than microadenoma of the pituitary, or if they had hyperventilation (more than 25 breaths per minute for at least one minute) during the procedure.

Pain and agitation were carefully avoided because they could induce ACTH secretion and cerebral metabolic rate of oxygen (CMRO2)/CBF changes, both of which were undesirable. The procedure was carried out in a noise-free environment, and accurate local anaesthesia was performed before venous cannulation. Arterial blood pressure was measured at five minute intervals by using an automated device with cuff inflation. Arterial oxygen saturation (SaO2) was continuously monitored using a pulse oximeter.

Statistical analysis

SjO2 values are presented as mean, upper (mean plus 2 standard deviations (SD)), and lower (mean minus 2 SD) limit. Precision of each point estimate was evaluated by 95% confidence intervals (95% CI).3 Comparison of the venous oxygen saturation in the jugular bulbs, inferior petrosal sinuses, and midlevel jugular veins was done using analysis of variance (ANOVA).

SjO2 values from this series were compared to those from the two historical series by Gibbs and colleagues (50 healthy individuals).
young volunteers) and Datsur and colleagues (26 healthy elderly volunteers). Data from the three series were compared by means of ANOVA.

Analysis of differences between right and left SjO2 in simultaneous samples was done using paired Student’s t test. In addition, the degree of agreement was evaluated according to Bland and Altman. The same procedure was applied to the data published in 1945 by Gibbs et al, in which bilateral measurements were performed in 25 patients with various psychiatric disorders. As suggested by the authors, seven patients were excluded because of data inconsistency.

In all cases two tailed tests were used and p < 0.05 was chosen to define statistically significant differences. Box plots were used for graphic presentation.

**RESULTS**

SaO2 and arterial blood pressure remained stable during the procedure. In two patients simultaneous catheterisation of jugular bulbs was not possible because of severe ear pain, in one the procedure was interrupted due to a contrast medium contamination from the facial veins, a factor that has been showed to avoid extracerebral blood contamination. Overall, 143 measurements were made in 12 patients. Haemoglobin was 130 g/l (SD 22).

Oxygen saturation was significantly lower in samples from the jugular bulb compared to inferior petrosal sinus and midlevel jugular vein (SmidjO2), and jugular bulb in the present series.

Differences between right and left SjO2 in simultaneous samples were not statistically significant, neither in the present series (t = 0.1978, two tailed p = 0.8481) nor in the Gibbs series (t = -0.1464, two tailed p = 0.8846); however, limits of agreement were wider in the latter. Results, expressed as mean difference (95% CI), and upper (95% CI) and lower (95% CI) limits of agreement were as follows: present study: 0.2% (-1.2 to 1.7); 3.7% (1.2 to 6.3); -3.3% (-5.8 to -0.7); Gibbs: -0.1% (-1.3 to 1.1); 6.5% (4.4 to 8.6); -6.7% (-8.8 to -4.6).

**DISCUSSION**

We found significantly lower SjO2 values in this series (44.7%) than reported in two old series (54.6%, 55.0%), the only ones in which SjO2 was measured in normal volunteers. The difference was not accounted for by the fact that patients in the present series had Cushing’s syndrome. In fact, all patients had a syndrome of recent onset, whose pathogenesis, whether due to microadenoma of the pituitary or paraendocrine tumours, had yet to be defined. In addition, patients with severe unstable hypertension, in whom uncoupling of CBF and CMRO2 may occur, were excluded.

Three facts are relevant to explain our results. First, we used a digital angiography system and vascular catheters were exactly positioned in the dome of the jugular bulb. In the Gibbs and Datsur series the catheter positioning in the jugular bulb was blind, and cervical x ray confirmation of the final catheter position was not performed. Therefore, extracerebral blood contamination from the facial veins, and as shown in this study, from the inferior petrosal sinuses may have occurred in some patients. Our results support this hypothesis showing that the SjO2 values in the old series were intermediate between SjO2 and SipsO2−SmidjO2 (extracerebral) in the present series. Second, blood samples in our study were withdrawn slowly, a factor that has been showed to avoid extracerebral blood contamination, provided that the catheter is correctly positioned in the jugular bulb. Third, we measured haemoglobin oxygen saturation by mean of a co-oximeter, the reference method based on three wavelength spectrophotometry, while Datsur et al used a two wavelength spectrophotometric method, and Gibbs et al the Van Slyke manometric method. The two latter methods overestimate oxygen saturation compared with the co-oximeter, particularly for the lower range of oxygen saturation, as is the case in venous samples.

**Normal SjO2 limit lower than previously recognised: does it matter?**

SjO2 values below the lower normal limit have been defined as jugular desaturation—that is, situations of critical inadequacy of CBF to CMRO2, “from norms defined by Gibbs and coworkers”, and have been proven in a single study to independently affect the outcome of severe head trauma. However, the methods on how to summarise insult data such as jugular desaturation have only recently been defined, while in previous studies the jugular desaturation was simply dichotomised as present or absent, based on Gibbs’ data. Therefore, a new limit could modify the result. More
importantly, it is suggested that jugular desaturations, variously defined as S\textsubscript{jO}\textsubscript{2} less than 50% or 54%, are treated aggressively, although benefits are unproven. A new normal limit further weakens the legitimacy of such treatments. This study included a small sample of patients and therefore conclusions should be taken cautiously. Due to the lack of invasiveness that can be attributed to the method itself, our results can be easily replicated. If the normal lower S\textsubscript{jO}\textsubscript{2} limit is confirmed to be as low as 46%, redefinition of “normality” applied to S\textsubscript{jO}\textsubscript{2} may have diagnostic, prognostic, and therapeutic implications.

REFERENCES
Sir David Ferrier MD, FRS

Carpenter ranked Ferrier’s cerebral localisation among the greatest advances in the physiology of the nervous system made in the past 50 years.1 It formed a direct link between Jackson and Sherrington, with both of whom he had worked.

Born in Aberdeen, Ferrier studied there under Alexander Bain, on whose advice in 1864 he visited Heidelberg, to study psychology with Helmholz and Wundt. Wundt had just (1862) completed the Beiträge zur theorie der sinneswahrnehmung that contained the first statement of his “physiological psychology”. Ferrier completed his medical training at Edinburgh where Thomas Laycock,2 inclining him towards neurology.

He worked in London from 1880, and was appointed Professor of Neuropathology, King’s College Hospital, in 1889. But his research began earlier at The West Riding Lunatic Asylum, Wakefield. There he showed that stimulation of the cerebral cortex could produce movements and fits, and that cerebral functions were localised in definable discrete areas.

Before him, in 1866, Friedrich Albert Lange (1828–75) had distinguished between localisation of function and localisation of symptoms. Broca, Bouillaud,3 Flourens,4 and others had tried to relate behaviour, language, and disease to different areas of the brain, but Franz Joseph Gall’s (1758–1828) phrenology was still accepted by many.5 Influenced by Bain and Spencer, Ferrier6 tested Hughlings Jackson’s notion that motor and sensory functions must be represented in an organised fashion in the cortex. Gustav Theodor Fritsch and Eduard Hitzig in 1870, using galvanic stimulation of the cerebrum in the dog, had recently shown that circumscribed cortical areas control movements of the contralateral limbs and that ablation of these areas caused weakness in these limbs. Their findings established electrophysiology as an experimental tool and showed the localisation of motor function in the hemispheres.

Ferrier used faradic rather than galvanic current to elicit movements that resembled primate walking, grasping, scratching, and thereby confirmed and extended the results of Fritsch and Hitzig. Ferrier localised smell in the uncus of the temporal lobe; hearing in the superior temporalopersonal convolution; and primitive vision in the angular gyrus, although this was later corrected by Munk’s discovery of the occipital visual cortex. Ferrier used both ablation and electrical stimulation to produce topography of localisation of function in several species.

Removal of the precentral gyrus, he found, caused paralysis and a hemiplegic position of the contralateral limbs. In 1876 he collected his results to produce his acclaimed The functions of the brain.7 This demonstrated that ablations and faradic stimulation of the brain were better than the galvanic techniques of Fritsch and Hitzig. He had thereby mapped sensory and motor areas across several species, thus expanding both understanding8 and localisation of motor and sensory functions.9,10

Ferrier also performed decerebration experiments to distinguish between voluntary and reflex movement, and examined the control of eye movements by electrical stimulation of the cerebellum. He was not obsessed by the anatomical localisation. The functions of the cerebral were sensorimotor.

“From the complexity of mental phenomena and the participation in them of both motor and sensory substrata, any system of localization of mental faculties which does not take both factors into account must be radically false.” He thus anticipated 20th century holistic concepts of cerebral function.

“Ferrier was more than an experimenter; he was, rather, a philosopher who did not philosophise but who experimented,” remarks Röch.11

By making lesions in the anterior frontal cortex, he deduced the effect on function: “while not actually deprived of intelligence...they had lost the faculty of attentive and intelligent observation.”

Thus, the frontal lobes might subserve the function of selection and inhibition of competing ideas.

He dedicated his work to Jackson:

“To Dr Hughlings Jackson who from a student to mature man...his work is as important as his wonder at the results of cerebral functions.”

Jackson, similarly, had been inspired by Spencer and frequently cited his writings. Sherrington, in turn, dedicated his lectures on The integrative action of the nervous system (1906) to Ferrier. And in his obituary notice of Ferrier for the Royal Society,12 Sherrington remarked:

“Ferrier has done the most important research in proving cerebral localization, in placing it at the centre of neurological interest, and in providing the basis for a ‘scientific phrenology’.”

He continued his clinical work applying these experimental findings to patients, and encouraging surgeons to operate on intracranial lesions; thus, Rickman Godlee said he was a powerful force in initiating brain surgery.

Among many honours, he received an Hon DS, University of Cambridge, in 1914 and in 1911 a knighthood. He was elected FRS in 1876, FRCP in 1877, and Goulstonian Lecturer in 1878. Not least of this great pioneer’s achievements was the foundation of the journal Brain, with Hughlings Jackson, Sir John Bucknill, and Sir James Crichton-Browne.
