Multiple painful sensory mononeuropathies (MPSM), a novel pattern of sarcoid neuropathy

Sarcoidosis is a granulomatous disease with the potential to affect many different organ systems. Approximately 5% of patients with systemic sarcoidosis have neurological involvement. Peripheral neuropathy occurs in up to 20% of these patients and is usually asymptomatic. Neurophysiological findings are consistent with primary axonal polyneuropathy. We report an unusual case of neurosarcoidosis, presenting with multiple painful sensory mononeuropathies (MPSM) and progressing to a symmetric confluent sensory neuropathy.

Case report

A patient in her 4th decade of life presented with a history of multiple sensory deficits. She first developed acute onset pain and numbness of the right little finger, followed by a change in taste over the anterior two thirds of the tongue, without facial weakness. Two months later, the patient developed numbness in the palmar aspect of all fingers with dysesthesia, intermittent burning, and throbbing pain. Three months later, the pain spread to involve the dorsal aspect of the right sural nerve, and numbness in the right posterior leg and over the left side of the trunk. The patient denied muscle weakness, painful radicular symptoms, or systemic features.

Physical examination was remarkable for the absence of sweet taste sensation over the anterior two thirds of the tongue, without facial weakness. Two months later, the patient developed numbness in the palmar aspect of all fingers with dysesthesia, intermittent burning, and throbbing pain. Three months later, the pain spread to involve the dorsal aspect of the right sural nerve, and numbness in the right posterior leg and over the left side of the trunk. The patient denied muscle weakness, painful radicular symptoms, or systemic features.

Laboratory investigations included a polyclonal increase in IgG component, with a low concentration band in the slow gamma region. Serum immunofixation confirmed absence of IgG. The presence of IgG by immunofixation confirmed a low concentration band in the slow gamma region. Serum immunofixation confirmed absence of IgG. The presence of IgG by immunofixation confirmed a low concentration band in the slow gamma region. Serum immunofixation confirmed absence of IgG. The presence of IgG by immunofixation confirmed the presence of IgG. The presence of IgG by immunofixation confirmed the presence of IgG. The presence of IgG by immunofixation confirmed the presence of IgG.

The remainder of the motor and sensory NCSs and needle electromyography, in the upper and lower extremities, were unrewarding. Blink reflexes were normal. Median nerve somatosensory evoked potential study revealed absent Erb's point potentials, bilaterally. Follow up NCSs, three months after the initial study, showed deterioration in the sensory NCSs, as demonstrated by the loss of left sural, left superficial peroneal, and both radial SNAPs. The sensory neuropathy had now become confluent and symmetrical. Motor NCSs remained normal. Non-contrast brain magnetic resonance imaging demonstrated three small subcortical white matter signal changes. Chest x-ray was normal. A chest computerised tomography scan demonstrated scattered centrilobular nodules, with thickening of the interlobular septa, and no hilar lymphadenopathy, which was consistent with sarcoidosis. Pulmonary function tests were normal. Abdominal fat pad aspiration biopsy was negative for amylloid. A right sural nerve biopsy revealed non-casing granulomas admixed with chronic inflammatory cells in the epineurium (fig 1A, B). Immunohistochromy of the lymphoid infiltrate was not possible because of technical difficulties. Sural nerve teased fibre preparations revealed myelin ovoids in numerous fascicles. Vasculitis was not seen. Biopsy of the right gastrocnemius muscle was normal. The patient was treated with prednisone, starting at 60 mg/day. At last follow up, 12 months after treatment onset, the patient continued to experience pain, but had not developed new neurological deficits. The patient was eventually lost to follow up.

Discussion

We report a case of sarcoid neuropathy presenting as MPSM and progressing to a symmetric confluent sensory polyneuropathy. This case was particularly challenging because the patient was not known to have sarcoidosis at presentation. The findings of a raised serum ACE concentration and lung computerised tomography imaging suggested a diagnosis of sarcoidosis. This was confirmed by demonstrating non-caseating granulomas in the epineurium of the right sural nerve. Although previous cases of pure sensory sarcoid neuropathy have been reported, they were distinct from our case in that the patients were already diagnosed with systemic sarcoidosis, or the symptom of pain was unreported. To our knowledge, our case is the first description of systemic sarcoidosis presenting as MPSM.

Sensory motor and pure motor polyneuropathies have been reported in systemic sarcoidosis. The relative frequency of different subtypes of sarcoaid neuropathies is uncertain. In a detailed clinical description of 10 cases of chronic sensory motor peripheral neuropathy, it was the most common form of non-cranial neuropathy. Other patterns included small fibre neuropathy, acute ascending paralysis similar to Guillain-Barré syndrome, and polyneuropathy, and lumbo-sacral plexopathy.

A potential mechanism of nerve damage in sarcoid neuropathy includes the local effects of tissue inflammation through release of noxious secretory products by activated inflammatory cells. Alternatively, ischaemia induced by necrotising vasculitis and direct mechanical compression of nerve fibres may lead to primary axonal degeneration, as supported by pathological findings of non-caseating granulomas in the epineurium and perineurium with periangiitis, panangiitis, perineuritis, and axonal loss. Furthermore, most neurophysiological findings were consistent with an axonal form of nerve injury.

In our case, the neurophysiological and pathological findings were consistent with primary axonal degeneration. We hypothesise that peripheral nerve injury may have resulted from mechanical compression of nerve fibres, because there was no evidence of vasculitis in our case. Moreover, the effects of local tissue inflammation could not be ruled out in this case.

Non-herpetic limbic encephalitis
associated with relapsing
polychondritis

Relapsing polychondritis is a generalised disorder characterised by recurrent inflammation of cartilaginous structures throughout the body, without recognised collagen disease or infectious disorders. Central nervous system involvement is rarely reported in this disorder. We describe the cases of two patients with relapsing polychondritis who presented with severe memory impairment and psychiatric features such as euphoria and hyperactive behaviours, leading to a diagnosis of non-herpetic limbic encephalitis.

Limbic encephalitis is caused by the herpes simplex virus (HSV) or by heterogeneous non-herpetic disorders (non-herpetic viruses, Hashimoto’s encephalopathy, central nervous system lupus, gliomatosis cerebri, intravascular malignant lymphomatosis, and para-neoplastic conditions). Clinical characteristics include cognitive dysfunction, severe memory impairment, seizures, depression, anxiety, and hallucinations. Magnetic resonance imaging (MRI) studies reveal selective unilateral or bilateral involvement of the limbic system, particularly the medial temporal lobe regions.

Our first patient was a 45 year old man referred to us because of subscale progressive mental confusion, euphoria, hyperactive behaviour, disorientation, and forgetfulness of recent episodes. He had a history of right sided conjunctivitis successfully treated with steroid and antibiotic ointment, shoulder stiffness, headache, low grade fever, and recent weight loss (6 kg).

On admission, the patient was disoriented, with an inappropriate gregarious affect, disjointed speech, confabulation, attention deficits, and memory impairment including anterograde and 1 year retrograde amnesia. His Mini-Mental Status Examination (MMSE) score was 11 (of a possible 30). He had no pyramidal or extrapyramidal disturbances or cerebellar ataxia. T2 weighted MRI showed bilateral, small, disseminated high intensity signals with vague margins in the medial temporal lobe, hippocampus, and insular cortex (fig 1A).

Laboratory studies showed white blood cell count 14.8 x 10^9/l (normal 3.9–9.3 x 10^9/l), platelet count 363 x 10^9/l (normal 150–450 x 10^9/l), β-thromboglobulin (β-TG) 94 μg/l (normal <50 μg/l), platelet factor 4 (PF-4) 30 ng/ml (normal <20 ng/ml), erythrocyte sedimentation rate (ESR) 42 mm/h. C reactive protein (CRP) 29 mg/l, ferritin 668 gg/l (normal <465 gg/ml), rheumatoid factor 145 IU/ml (normal <20), and antinuclear antibodies (ANA) 1:40. Serum tests were negative for myeloperoxidase antineutrophil cytoplasmic antibodies, anti-DNA, anti-SSA/SSB, and anti-RNP. Thyroid function and vitamin B12 and B12 levels were normal. Syphilis, HSV-1, HSV-2, herpes zoster virus, human herpes virus 6, cytomegalovirus, Epstein-Barr virus, measles, rubella, and mumps were serologically excluded. No neoplasm was detected.

Rubella, and mumps were serologically excluded. No neoplasm was detected.

Our patients responded dramatically to early treatment with high dose intravenous corticosteroids followed by an oral corticosteroid, although mild amnesia with confabulation remained in both cases. The atrophy of the medial temporal lobe and dilatation of the temporal horns of the lateral ventricle seen on MRI after treatment indicated irreversible ischaemic damage. Although we cannot exclude the possibility that the brain atrophy in the medial temporal regions resulted from the corticosteroid therapy, the bilaterally reduced blood flow was seen on SPECT images of the temporal lobes (data not shown), suggesting that the atrophy was not caused by corticosteroid treatment.
Although relapsing polychondritis is a rare disorder, it should be considered in the differential diagnosis of neurological complications such as limbic encephalitis, and it is worth noting that steroid therapy may be beneficial.

Diffusion tensor MRI of the cervical cord in a patient with syringomyelia and multiple sclerosis

Diffusion tensor magnetic resonance imaging (DT-MRI) is a powerful technique which provides quantitative information about structural and orientational features of the central nervous system. Development of DT-MRI based technology for identification for individual fibre tracts is important; this will allow detailed assessment of the damage to the cervical cord and its sensitivity to artefacts related to the cerebrospinal fluid, cardiac and respiratory motions, spinal cord DT-MRI presents some technical difficulties and has underpinned the potential of DT-MRI to provide a complete picture of cord damage in various neurological disorders. Compared with conventional MRI, it enabled us to obtain quantitative information of the pathological characteristics of the tissue beyond the abnormalities visible on MRI. This shows promise in overcoming the well known discrepancy between aspects of conventional MRI and the clinical findings, reported in numerous neurological conditions. Moreover, clinical application of cord DT-MRI tractography may have prognostic value with regard to functional recovery after acute inflammatory or demyelinating pathologies, as it may enable us to investigate the residual integrity of clinically important pathways.

ipsilateral axial lateropulsion as an initial symptom of vertebral artery occlusion

Case reports

A 58 year old man noticed an unsteady gait when he woke up. He was unable to keep standing and fell several times to the left. On the next day, he visited our clinic. He denied vertigo, diplopia, hiccup, dysphagia, speech disturbance, numbness, and muscle weakness. On admission, ocular movements were normal in all directions. Spontaneous or gaze evoked nystagmus was not detectable with or without Frenzel’s glasses. He had no skew deviation, ocular lateropulsion, saccadic pursuit, ocular dysmetria, or Horner’s syndrome. Electrical stimulation of the right upper limb was not painful and no pathological reflexes were noted. There was no nasal voice, hoarseness, or dysarthria. The tongue did not deviate on protrusion. Other cranial nerve functions were intact. He had no weakness. Coordination of the extremities was intact. He was unable to keep standing without assistance due to marked lateropulsion to the left. Deep tendon reflexes were normal. He had no pathological reflexes. Facial sensation was intact and was able to differentiate between cold and pinprick in the upper and lower limbs. Position sense was intact in the lower limbs. Magnetic resonance imaging (MRI) showed an acute infarct in the left lateral medulla (fig 1A) and a flow signal abnormality in the left VA. Magnetic resonance angiography (MRA) confirmed an occlusion of the left VA. On day 3, he started to improve. However, he noticed that he was unable to differentiate between cold and warm water with his right lower leg and foot while bathing. On examination, he noted thermal and pain sensory loss in his right lower leg and foot. Posturographic data demonstrated abnormal body sway from left forward to right backward. He was discharged on day 10 with only slight unsteadiness. A 55 year old man noticed a strong tendency to fall to the right on attempting to stand or walk. A few days after the onset, he noticed that he was unable to perceive coldness in his left buttock and thigh while sitting on a toilet. He did not have headache, vertigo, hiccup, dysphagia, hoarseness, numbness, or weakness. He visited our clinic on day 6. He had no Horner’s syndrome, skew deviation, ocular lateropulsion, ophthalmoplegia, dysarthria, bulbar palsy, muscle weakness, or limb ataxia. He did not have spontaneous or gaze evoked nystagmus with Frenzel’s glasses. He could not resist the right on attempts to stand with his eyes closed. Deep tendon reflexes were unremarkable. He had no pathological reflexes. Sensation for light touch and position was intact. Pain and thermal sense was impaired in his left buttock and lower limb. MRI failed to show lesions in the brainstem or cerebellum. MRA demonstrated an occlusion of the right VA. He was treated with 100 mg of aspirin. Over 4 weeks, axial lateropulsion subsided, while the sensory impairment persisted.

Discussion

Isolated axial lateropulsion occurs with ischemic lesions in the inferior portion of the cerebellum and tonsil and with a demyelinating lesion of the superior and inferior cerebellar peduncles.4 Lee et al reported a patient with lateral medullary infarction who showed a gaze evoked horizontal nystagmus as well as axial lateropulsion.3 Thus, the critical structure for lateropulsion remains to be elucidated. The patients described here did have pain and thermal sensory impairment in the contralateral lower limb, which is attributed to a lesion in the ventrolateral part of the spinothalamic tract. A very small lesion located superficially in the lateral medulla causes an atypical spinothalamic sensory deficit, which in some cases appears a few days after the onset of other symptoms. In the present cases, however, it is likely that the pain and thermal sensory deficit was present initially but was not noticed. An occlusion of the VA may have caused ischaemia in the territory of the short circumferential medullary artery directly arising from the distal VA. Structures located dorsal to the spinothalamic tract, including the spinal trigeminal tract and nucleus, and the ambiguous and vestibular nuclei were probably spared, because these patients did not have facial sensory impairment, pharyngeal or laryngeal palsy, or nystagmus. Conversely, it is highly likely that the vestibulospinal tract was involved, because it is located just ventromedial to the spinothalamic tract in the medulla. The vestibulospinal tract is considered to play an important role in the maintenance of posture by exerting strong excitatory influences on extensor muscles and inhibitory influences on flexor muscles. Thus, interruption of the vestibulospinal tract decreases extensor muscle tone of the trunk and lower limb on the side of the lesion, which is likely to cause ipsilateral axial lateropulsion. The anterior spinocerebellar tract was likely to be involved, because it is located just dorsolateral to the spinothalamic tract in the medulla. It is possible that axial lateropulsion is associated with a lesion of the spinocerebellar tract. In the case reported by Bertholon et al., axial lateropulsion may have been caused by ipsilateral lesions of the anterior and posterior spinocerebellar tracts, which are incorporated in the superior and inferior cerebellar peduncles. Given that the vestibulospinal and spinocerebellar tracts have no projections to the ocular motor system, it is natural that these two patients did not have nystagmus or oculomotor disorders. The present findings raise the possibility that the lateral medullary lesions in the Wallenberg syndrome is attributable to lesions of the vestibulospinal and spinocerebellar tracts as well as central vestibular pathways.

References

The first patient, a boy, was referred at the age of 3 months because of a large bone defect (PFM) identified on physical examination. The mother (22 years old), aunt (25 years old), and grandfather (55 years old) also had PFM, but smaller than the child’s, showing an age related size variation. Molecular analysis, reported elsewhere, showed that this family had an ALX4 mutation (PFM type II). History, neurological examination, and neuroimaging evaluations were obtained from three relatives. The aunt refused further analysis. Electroclinical investigation consisted of a detailed clinical history, review of charts, and video electroencephalogram (V-EEG) monitoring. Neuroimaging evaluation consisted of helical computed tomography scans of the head (with post-processing three-dimensional views of the cranial vault), 1.5T magnetic resonance imaging (MRI) at three orthogonal planes with conventional SE (before and after intravenous paramagnetic contrast administration), and magnetic resonance venography.

At the age of 4 years, the patient was referred to our laboratory for elucidation of paroxysmal events, described as brief periods of “blindness”. He was born at term, by caesarian section after an uneventful pregnancy. During follow up, physical and neurological examinations revealed normal neurological development and physical growth. The mother (22 years old), aunt (25 years old), and grandfather (55 years old) also had PFM, but smaller than the child’s, showing an age related size variation. Molecular analysis, reported elsewhere, showed that this family had an ALX4 mutation (PFM type II). History, neurological examination, and neuroimaging evaluations were obtained from three relatives. The aunt refused further analysis. Electroclinical investigation consisted of a detailed clinical history, review of charts, and video electroencephalogram (V-EEG) monitoring. Neuroimaging evaluation consisted of helical computed tomography scans of the head (with post-processing three-dimensional views of the cranial vault), 1.5T magnetic resonance imaging (MRI) at three orthogonal planes with conventional SE (before and after intravenous paramagnetic contrast administration), and magnetic resonance venography.

Electroencephalographic tracings showed frequent, sharp waves over the left posterior quadrant in the child (fig 1A). Although V-EEG was done, we did not register his seizures because of their sporadic nature. The mother had a normal current EEG, but previous EEG reports described the same abnormality as in her child.

The grandfather had no current neurological or cognitive defects. He denied a history of seizures, syncope, migraine, or other paroxysmal events. His EEG was normal.

Neuroimaging investigation with 1.5T MRI showed a malformation of occipital infolding, suggestive of a polymicrogyric cortex over the posterior regions in all three patients, although this was more prominent in the child (fig 1B).

This family had the classic phenotype for PFM, in this case type II (ALX4 mutation), including age related expression with regard to the size of the foramina. In contrast to the current idea that PFM is not associated with neurological disorders, the child and his mother had epilepsy with occipital lobe seizures. Reviewing previous studies, Kyte described one patient with identical epilepsy and EEG features as seen in our patients, including the age related improvement. An important issue in this family, not previously reported, is the earlier onset and higher frequency of events in the child. Analysis of this family showed an intrafamilial variability, with a more severe and earlier presentation of epilepsy in the youngest member. Our findings suggest a generation related modulation of the clinical picture, which may explain why some patients may present with a clinical condition whereas others remain asymptomatic.

Our family had an ALX4 mutation, but there is no evidence of genotype–phenotype differences between patients with PFM type I (MSX2 mutation) and II (ALX4 mutation). In an experimental study, Satokata et al described Msx-2 mutant mice with seizures accompanied by abnormal development of the cerebellar cortex, which suggested a structural malformation as the cause of seizures, as seen in our patients. The association of cortical anomalies and epilepsy is well known and the neuroimaging study in our family showed the coexistence of a cortical malformation on the posterior region in the three relatives with PFM, including the asymptomatic member. Reddy et al described cortical and vascular anomalies, corroborating that these findings may not be uncommon, and are now being identified because of advances in neuroimaging.

Malformations of cortical development are seen in some syndromes found with other diseases that have a well known genetic basis. Polymicrogyria seems to result from genetic or environmental factors, or both. In our patients, although a genetic anomaly was found, the abnormal cortex overlies vascular territories. This may seem contradictory, but it is possible that the cortical anomalies in this family are the consequence of a vascular abnormality which, in turn, could have been caused by the genetic anomaly.

In conclusion, we suggest that some cases of PFM are not as benign as thought previously. From a practical point of view, the documentation of a family with neurological symptoms because of cortical abnormalities indicates that more extensive neuroimaging is recommended for patients with PFM, in addition to the investigation of families, especially when patients are symptomatic.

Baroreflex failure secondary to paraneoplastic encephalomyelitis in a 17 year old woman with neuroblastoma

Baroreflex failure is a rare cause of postural hypotension but should be considered in any patient with a diffuse central nervous system disease involving the brainstem. Paraneoplastic encephalomyelitis (PEM) is such a disease and, although rare, is becoming more frequently diagnosed because of improved imaging and specific antibody testing. We present the first case of baroreflex failure secondary to PEM. In January 2002, a 17 year old woman presented with a 3 week history of pain in the right shoulder which spread down the forearm to the radial border of her hand. She had also become anorexic and lost 18 kg over 3 months. A mild resting tachycardia was noted but there were no objective neurological signs, and routine blood tests, including inflammatory markers, were normal. In March, both pupils became dilated, non-reactive to light or near stimuli, and my tonic (that is, Holmes-Adie pupils). Limb reflexes were decreased and nerve conduction studies demonstrated a mild motor-sensory polyneuropathy. The aetiology of her anorexia was thought to be psychological and over the next 3 months she was treated with sedatives, antidepressants, and motility agents. She regained 12 kg but her neurological abnormalities persisted, and she developed psychomotor retardation and symptomatic postural hypotension. In July she underwent tilt testing and autonomic studies.

The patient was positioned horizontally on the tilt table and continuous blood pressure (BP) was monitored using digital plethysmography, stroke volume was derived from the arterial pulse wave, heart rate (HR) from the ECG, and muscle sympathetic nerve activity (MSNA) from the right peroneal nerve using the microneurographic technique.¹ The antibody testing was positive for immunofluorescent anti-neuronal nuclear antibody type 1 (ANNA-1, also known as “anti-Hu” titre 1:30 720), confirmed by western blot against native neuronal antigen. In October 2002 a mass was found in her right neck and biopsy demonstrated a neuroblastoma. Further bone scanning and bone marrow biopsies demonstrated no evidence of metastatic disease. She was treated with chemotherapy followed by surgery and local radiotherapy. Repeat scanning demonstrated complete remission. Her gastrointestinal symptoms improved, and the postural hypotension, pupillary signs, and psychomotor retardation remained stable.

In retrospect, all the clinical findings are consistent with PEM, consisting of: (a) limbic encephalitis causing psychomotor retardation, (b) sensory neuropathy affecting the limbs, (c) autonomic dysfunction including Holmes-Adie pupils and impaired baroreflex modulation of heart rate and vasoconstriction, and (d) enteric neuropathy causing gastrointestinal dysmotility.² As we have demonstrated, the diagnosis may be difficult. This is primarily because paraneoplastic syndromes are rare (the incidence is less than 0.1% in cancer patients), neurological symptoms usually predate the discovery of the tumour, and the antibody tests are not widely available.³ Psychomotor retardation and anorexia were initially thought to be secondary to a psychological disorder, despite the neurological findings and the demonstration of delayed gastric emptying. The tilt test results indicated a polyneuropathy as the primary cause of the patient’s symptoms. Following exclusion of common neuropathic aetiologies, the diagnosis of PEM was made following the finding of high titre ANNA-1 antibody and the neuroblastoma. ANNA-1 antibody recognises a family of RNA binding proteins (35–40 kDa) in neurons and certain tumours including small cell lung carcinoma and neuroblastoma which share a common ectodermal origin.³ The nuclear antigens are expressed by all small cell lung carcinomas and most neuroblastomas although the antibody is not usually present.
Most paraneoplastic syndromes associated with neuroblastoma have been reported in young children with cerebellar ataxia, myoclonus, and opsoclonus. ANNA-1 antibodies are usually present in patients with small cell carcinomas and paraneoplastic gastroparesis but have not been previously reported in association with neuroblatoma and autonomic dysfunction.1 Although new antibodies continue to be reported in association with paraneoplastic neurological disorders, the majority of patients with subacute onset of autonomic failure or gastrointestinal dysmotility are considered idiopathic. The most specific marker autoantibody recognised so far is directed at postsynaptic acetylcholine receptors in autonomic ganglia, and was not detected in our patient.4 We suspect that the primary mechanism for her severe postural hypotension was baroreflex failure resulting in increased, rather than decreased, basal efferent sympathetic activity. Baroreflex failure refers to loss of inhibitory feedback from the arterial baroreceptors to the brainstem. The baroreflexes are the most important mechanism for maintaining blood pressure during rapid changes in posture and central blood volume. Baroafferents may be damaged in the periphery (for example, arterial baroreceptors during carotid endarterectomy) or, as we suspect in this patient, the central nervous system where they enter the superior medulla.5 We hypothesise that baroreflex failure caused severe postural hypotension by two mechanisms: firstly, the immediate vasconstrictor and AVP responses to changes in central blood volume were decreased; and secondly, increased sympathetic activity at rest mediated chronic splanchic vasoconstriction and decreased venous capacitance. This caused decreased venous return and an exaggerated fall in cardiac output in response to upright posture. Efferent sympathetic failure was unlikely because MSNA activity was increased at rest and increased normally (with resulting hypertension) during the diving reflex. The diving reflex is mediated by increased sympathetic output from the medulla in response to trigeminal sensory (as opposed to baroafferent) pathways.

Acknowledgements
We are grateful for the assistance of Professor Vanda A Lennon, Mayo Clinic, Rochester, MN who undertook paraneoplastic autonomic screening and identified the ANNA-1 antibody. Dr Carina Miles reported the tumour biopsy. The figure was tested by asking the patient to follow the optokinetic nystagmus was tested for by

Acquired ocular motor apraxia from bilateral frontoparietal infarcts associated with Takayasu arteritis

The relatively rare syndrome of acquired ocular motor apraxia is characterised by difficulty in initiating saccades to command and to visual targets, usually in all directions.6

Case report
Our patient was a 52 year old left handed and non-literate man. He was admitted to a local hospital with the complaint of acute and persistent thoracic and epigastric pain radiating to his back. Five days later he developed acute loss of consciousness and was sent to our hospital.

Blood pressure was 170/100 mm Hg from the right arm and 160/100 mm Hg from the left, the right femoral artery was pulseless, and the epigastrum was painful on palpation. He was stuporous, disoriented, and his cooperation was limited to simple commands only. He had bilateral ptosis with his eyes fixed in the primary position. Convergence was absent. However, an oculocephalic reflex could be elicited both in horizontal and vertical directions. His left nasolabial sulcus was somewhat reduced. He had paresis of both his arms and his left leg, while the motor strength in his right leg was almost completely normal. Hoffman and Babinski signs were positive on the left side, with hyperreflexia. The tendon reflexes were normal on the right side and no pathological reflexes were elicited. He had urinary incontinence.

On the third day of admission he appeared aphaetic. Although his thinking was slowed, and his affect was flattened, he could answer simple questions and obey simple commands. He still had difficulty in understanding complex orders. His tics had resolved but the hypotonia in the left upper extremity was more pronounced. His eyes were still fixed in the primary position.

In the following few days, when he was no longer stuporous, he was observed to execute spontaneous eye movements in all directions without associated head movements, but he was unable to carry out any eye movements when he was instructed to gaze at an object. He was also unable to execute pursuit movements, and there was no optokinetic nystagmus response. On bedside examination, optokinetic nystagmus was tested for by rotating a drum vertically and horizontally 24 hours before his eyes. Foetal smooth pursuit was tested by asking the patient to follow the movement of a target light produced by a light source. Examination of the visual fields with confrontation was normal. He also had no visual extinction. Two months after admission, the patient was transferred to a rehabilitation centre, showing full cooperation and orientation and with his eye movements partly recovered. He had no visual hemianopia or right–left disorientation. His muscle strength had only mildly improved and he had severe hypotonia in his parietal extremities, with clonus of the left leg. A month later he was discharged from the rehabilitation centre without any eye movement abnormality. The oculocephalic reflexes were spared throughout the course of the illness.

Blood studies showed a leucocytosis (14 600 WBC/mm3) and an inflammatory reaction (erythrocyte sedimentation rate 124 mm/h, C reactive protein 110 mg/l). Cranial computed tomography (CT) showed hypodense lesions of cortical grey matter at the level of both cerebral convexities. Cranial magnetic resonance imaging (MRI) showed subacute infarcts involving the cortical grey matter of both frontal and parietal border zones bilaterally. The frontal eye field (FEF, at the intersection of the precentral sulcus and the superior frontal gyrus) was spared (fig 1A). Both supplementary motor fields (SMF, the superior frontal gyrus) were spared (fig 1A). Coronal section through the parietal lobe revealed that the intraparietal sulcus (PEF) was involved bilaterally (fig 1A), whereas both supplementary fields (SEF, the superior frontal gyrus) were spared (fig 1A). Contrast enhanced MRA showed irregularity of the vessel wall beginning from the aortic arch and extending the abdominal aorta (fig 1C). Cutaneous biopsy from the abdomen supported a diagnosis of vasculitis. The patient was diagnosed as having Takayasu arteritis.

Comment
The case is a good example of “acquired” ocular motor apraxia. It appears that both frontal eye fields of the frontal cortex (PCC) was spared (fig 1B). Three dimensional time of flight magnetic resonance angiography (MRA) showed no abnormality of the cerebral vessels. Contrast enhanced MRA showed irregularity of the vessel wall beginning from the aortic arch and extending the abdominal aorta (fig 1C). Cutaneous biopsy from the abdomen supported a diagnosis of vasculitis. The patient was diagnosed as having Takayasu arteritis.
bihemispheric infarcts.¹ Our patient could not be evaluated for any apraxia of his extremities or for optic ataxia because of the degree of paresis in both his arms. He might also have had an optical ataxia during the period when he had anosognosia and right–left disorientation. The development of a substantial degree of paresis with hypertonia in the first days of the ischaemic insult, and the continuation of these symptoms after ocular motor apraxia had resolved, may suggest that the anterior border zone areas were affected to a greater degree than the posterior border zone areas.

For this reason the functions of both the FEFs might have been undertaken by the PEFs. It seems likely that this role could be assumed by other areas, such as the posterior areas, as an adaptive response after injury.¹ Bilateral damage to the PEFs may result in severe impairment of pursuit movements.¹ The posterior cingulate cortex (PCC)—which is known to show neuronal activity during pursuit movements—was spared in our patient. However, the medial superior temporal lobe (MST), located close to the intraparietal sulcus, was possibly damaged. This area is known to be implicated in pursuit eye movements from single cell recording studies in the monkey.¹

We observed in our patient that ocular apraxia and pursuit movements of the eyes began to resolve simultaneously. This observation may suggest that recovery in the PEFs might have occurred first and have compensated for the FEFs. Recovery of spontaneous saccades in the first few days of ischaemia might indicate that the SEFs, which are assumed to be responsible for these eye movements, were not seriously damaged.
