Clinical characteristics of multiple sclerosis in Västerbotten County in northern Sweden

P Sundström, A Svenningsson, L Nyström, L Forsgren

Background: Most clinical data for multiple sclerosis are hospital based—that is, derived from patients referred to clinics specialising in the disease.

Objectives: To present data derived from two population based multiple sclerosis populations, an incidence cohort and a prevalence population, from Västerbotten County, northern Sweden.

Methods: The two populations were identified from multiple sources, and case ascertainment was assured through a personal clinical review, including interviews and examination of the patients.

Results: Characteristics at onset for the different clinical subtypes of multiple sclerosis are presented, including the clinical spectrum of the first attack, the anatomical correlation between the first and second attacks, sex distribution, and disability distribution.

Conclusions: Based on the comparison of present and earlier natural history data, multiple sclerosis appears to be a slightly more benign disease than previously recognised.

Up to year 2001, data collected from multiple sources were used to make case identification as complete as possible. Case ascertainment and reliability of clinical data were assured from medical records, the results of magnetic resonance imaging (MRI), cerebrospinal fluid (CSF) electrophoresis analysis, and other laboratory and paraclinical tests, together with follow up interviews and neurological examinations including expanded disability status scale (EDSS) assessment.

Clinical judgement determined the use of data received from either interviews or medical records when these data were in conflict. If new information emerged from interviews, such as an earlier first attack than was previously recorded, we retrieved the corresponding medical records, if available. Medical records written less than five years after disease onset were available in 92% of incident cases and 82% of prevalent cases. Interferon β treatment was approved in 1995 in Sweden, but only five cases were treated before the end of the incidence period coinciding with the prevalence day. The use of immunosuppressive treatment other than corticosteroids at relapses was likewise limited to a handful of patients. Clinical outcome was not affected by participation in clinical trials.

Definitions

A specification of symptoms (table 3) to be considered as the first manifestation of relapsing-remitting multiple sclerosis (RRMS) was used to define disease onset, “defined onset”, in RRMS cases. Any preceding symptoms possibly constituting the onset, “possible onset”, of RRMS were also recorded. When not specified otherwise, “defined onset” was used for calculations on age at onset and disease duration. The duration, sensory/motor distribution when applicable, and

Abbreviations: DSS, disability status scale; EDSS, expanded disability status scale; PPMS, primary progressive multiple sclerosis; PRMS, progressive relapsing multiple sclerosis; RRMS, relapsing-remitting multiple sclerosis; SPMS, secondary progressive multiple sclerosis.
grade of remission of the “defined onset” attack were recorded. Using the same specification as for “defined onset” symptoms, the second attack, if present, indicating dissemination in time and space was also recorded in RRMS cases. The year of onset of progressive neurological symptoms was recorded for primary progressive (PPMS), secondary progressive (SPMS), and progressive-relapsing multiple sclerosis (PRMS). If a progressive disease course was preceded by only a “possible onset” attack believed to represent the true onset of multiple sclerosis, the disease course was classified as SPMS, and the year for SPMS onset was regarded as the year of “defined onset”. The year of the prevalence day was used for calculation of disease duration. The exception was when clinical data were also analysed, when the year for data collection was used.

**Follow up**

As part of the clinical review of cases, a follow up interview was done between August 1997 and December 2001, median year 1998, for 123 of 133 incident cases (93%) and 364 of 399 prevalent cases (91%). In 57 prevalent cases, the interview information was at least partially retrieved from participating relatives or caregivers. Incident cases not participating in the follow up interview had shorter disease duration; however, this was not statistically significant compared with interviewees. The opposite non-significant difference was true for prevalent cases. Follow up neurological examinations including EDSS assessments were undertaken by P5 in 95 incident and 324 prevalent cases.

**Statistical methods**

SPSS was used for computerisation and statistical analysis. The variables age and duration are skewed; thus only the median has been presented. The Kruskal–Wallis test was used to test the difference between total and partial remission of the first attack. For all other tests of the association between first and second attack in the optic nerve, brain stem/cerebellum, or spinal cord region (table 3) were analysed separately. Cases with multifocal onset were excluded from this analysis. In all, 40% more cases than expected were found to have had their first and second attack in the same region (70 actual vs. 50 expected, p = 0.004). This was most pronounced in cases with optic nerve and brain stem/cerebellar attacks, where there was a 37% and 74% increased likelihood of having the second attack in the same respective region. This finding was achieved despite the fact that the second attack had to show dissemination in space. Although non-significant, the same finding was confirmed in incident cases (n = 40), for which a 37% increased likelihood of having the first and second attack in the same anatomical region was found (21 actual vs. 15.3 expected, p = 0.22). The variables age and duration are skewed; thus only the median has been presented. The Kruskal–Wallis test was used to test the difference between total and partial remission of the first attack. For all other tests of the association between first and second attack in the optic nerve, brain stem/cerebellum, or spinal cord region (table 3) were analysed separately. Cases with multifocal onset were excluded from this analysis. In all, 40% more cases than expected were found to have had their first and second attack in the same region (70 actual vs. 50 expected, p = 0.004). This was most pronounced in cases with optic nerve and brain stem/cerebellar attacks, where there was a 37% and 74% increased likelihood of having the second attack in the same respective region. This finding was achieved despite the fact that the second attack had to show dissemination in space. Although non-significant, the same finding was confirmed in incident cases (n = 40), for which a 37% increased likelihood of having the first and second attack in the same anatomical region was found (21 actual vs. 15.3 expected, p = 0.22).

**RESULTS**

**Disease duration**

Year of onset in the prevalence population ranged from 1935 to 1997, and the median (mean) disease duration was 15 (18) years. Median (mean) disease duration was 15 (18) years in RR/SPMS and 12 (15) years in PPMS prevalent cases (p = 0.008).

**Age at onset and clinical course**

The clinical course distribution was similar in the incidence and prevalence group (table 1). Ages at onset by sex and clinical course are presented in table 2. Median age at onset was higher for incident cases than for prevalent cases (34 v 30 years; range 14 to 63 v 7 to 68; p = 0.024). There was no significant difference between female and male subjects. Median age at onset for prevalent PPMS cases was 10 years higher than for prevalent RR/SPMS cases (39 v 29 years; range 15 to 68 v 7 to 58; p < 0.001). Median age at “possible onset” was lower than “defined onset” for prevalent RR/SPMS cases (27 v 29 years). This difference was as great as 29 years in individual cases in the incidence population and 30 years in the prevalence population. Median age at onset for prevalent PRMS cases was 32 years (n = 13, not shown in the table).

Table 3 describes the distribution of onset attack symptoms among RR/SPMS incident and prevalent cases. In incident (n = 3) and prevalent (n = 20) RR/SPMS cases with multifocal onset, the predominating onset symptom was chosen.

Prevalent cases with total remission had a lower median age at onset (29 years, n = 118) than patients with a partial remission of their first attack (32 years, n = 83) (p = 0.035) (cases with multifocal onset were excluded, and only information in original medical records was used for both). The maximum duration of the onset attack in cases with total remission was 12 months. There was a weak association between duration of first attack and age at onset (r = 0.2; p = 0.05), found only in incident cases.

In 39% of incident and 32% of prevalent RR/SPMS cases, a “possible onset” symptom preceded the “defined onset”. A majority of these symptoms were sensory or motor symptoms not included in table 3—that is, symptoms not clearly involving an entire limb or sensory symptoms with facial or truncal localisation. Visual symptoms (perhaps from an undiagnosed optic neuritis), possible brain stem symptoms, neuropathic pain, dysuria, psychiatric symptoms, and epileptic seizures formed the remainder of symptoms judged to constitute the onset of RRMS.

**Second manifestation in RR/SPMS**

The time to the second manifestation of RR/SPMS (attack or progressive symptoms) was analysed in 90 incident cases after excluding cases with only one attack of the symptoms listed in table 3 at follow up (n = 12) and cases where the onset of SPMS constituted “defined onset” (n = 4). The median duration (and range) between the first and second definite multiple sclerosis manifestation was 2 (0 to 9) years. In 15 of the 90 incident cases the second manifestation of multiple sclerosis was the conversion to SPMS.

Prevalent RR/SPMS cases (n = 141) having had both their first and second attack in the optic nerve, brain stem/cerebellum, or spinal cord region (table 3) were analysed separately. Cases with multifocal onset were excluded from this analysis. In all, 40% more cases than expected were found to have had their first and second attack in the same region (70 actual vs. 50 expected, p = 0.004). This was most pronounced in cases with optic nerve and brain stem/cerebellar attacks, where there was a 57% and 74% increased likelihood of having the second attack in the same respective region. This finding was achieved despite the fact that the second attack had to show dissemination in space. Although non-significant, the same finding was confirmed in incident cases (n = 40), for which a 37% increased likelihood of having the first and second attack in the same anatomical region was found (21 actual vs. 15.3 expected, p = 0.22).

**Conversion to SPMS**

Fifty per cent (161 of 325) initially RRMS prevalent cases were known to have entered SPMS at follow up. Median time from the onset attack to SPMS was 10 years (range 0 to 36, n = 150) for prevalent cases with known year of SPMS onset. Median age at onset of SPMS for these cases was 42 years (range 14 to 74), which did not differ significantly from the age of onset for PPMS prevalent cases.

In 23 cases with a disease duration exceeding 25 years, no conversion to SPMS could be documented. Median EDSS in these patients was 3.5, opposing any significant under-estimation of SPMS conversion. The support from CSF and MRI for a diagnosis of multiple sclerosis in these 23 elderly cases was if anything more solid than in the SPMS converted cases with the same disease duration.

The clinical course was or had been RRMS in 106 incident cases (80%); 27 (25%) of these had entered SPMS at follow up after a median disease duration of five years. Progression in every incident SPMS case was characterised by sensory-motor symptoms predominating in the lower extremities—
that is, a parasyndrome—except for one case with a progressive opticopathy.

**PPMS onset symptoms**

Disease onset in PPMS incident cases was compatible with a sensory or motor parasyndrome in all but four patients, three of whom had hemisymptoms initially and one had cerebellar onset symptoms. Except in eight cases, the onset was consistent with a sensory or motor parasyndrome in all PPMS prevalent cases; in six cases hemisymptoms predominated initially, and one each had cerebellar and optic symptoms.

**Sex ratio**

The sex ratios (female to male) for all prevalent cases, RR/SPMS prevalent cases, and PPMS prevalent cases were 1.9,
2.3, and 1.0, respectively. The corresponding figures for incident cases were 1.8, 2.1, and 1.1. The sex ratio in incident and prevalent PPMS cases was the same regardless of age at onset.

We further analysed whether subgrouping cases for age and the anatomical region of the first attack affected the sex ratios. The onset attack symptoms were aggregated into four groups based on anatomical region (table 3): optic nerve, brain stem/cerebellum, spinal cord, and cerebral/unclear. Table 4 shows the female to male ratio by age at onset and anatomical region of first attack for 316 prevalent RR/SPMS cases, for all of which the sex ratio was 2.2.

The two most pronounced deviations in sex ratios were first, that an optic nerve onset was an uncommon presentation in older male subjects, and second, that a spinal cord onset was more frequent in younger female subjects.

### Disability

EDSS was assessed in 389 prevalent and 130 incident cases. We tried not to use assessments done during an exacerbation and, when information in medical records was used, to choose an examination date as close to the prevalence day as possible. Median year for assessment of prevalent cases was 1998, 83% of assessments being performed in 1997 to 1998.

The distribution of EDSS was: 0 to 2.5 in 36% (n = 139), 3.0 to 5.5 in 27% (n = 104), 6.0 to 7.5 in 21% (n = 82), and 8.0 to 9.5 in 16% (n = 64). EDSS distribution by age group and sex is shown in fig 1. Figure 2 shows relative EDSS distribution by disease duration.

Median year of EDSS assessment in incident cases was 1998 (range 1993 to 2001). After a median disease duration of five years (range 0 to 10), the EDSS distribution was: 0 to 2.5 in 62% (n = 81), 3.0 to 5.5 in 21% (n = 27), 6.0 to 7.5 in 14% (n = 18), and 8.0 to 9.0 in 3% (n = 4).

### DISCUSSION

The onset of multiple sclerosis

This study provides population based clinical data on onset symptom, second attack, clinical course, and EDSS distribution in an incidence population and a prevalence population. The determination of multiple sclerosis onset is fundamental for this discourse. Onset symptoms in multiple sclerosis have been categorised previously in different ways. To our knowledge the only effort to produce a standard allowing comparisons of epidemiological studies is the list of onset symptoms adopted here. Some items in the original list were found to be of little or no use. On the other hand, the present “defined onset” criteria did not include all the symptoms judged to represent the true disease onset. Thus nine prevalent and four incident cases were classified as having SPMS in the absence of any “defined onset” attack. In this material, data for both “possible” and “defined” onset are given, the former being more sensitive and the later more specific. The choice of onset definition significantly affected the median age of onset by two years in prevalent RR/SPMS cases. As far as comparison is possible, the present distribution of “defined onset” symptoms appears to be comparable to the findings in other studies. We believe a standard of onset symptoms is required for a thorough comparison of epidemiological studies of multiple sclerosis.

### Age at onset

Incident cases had a greater age at onset than prevalent cases. Possible explanations are that patients with early onset have a longer interval between the first and second attacks and are

but only variants of the same disease. The view that RR/SPMS and PPMS are not different entities, example, 71% of incident most favourable description of the disease course. For sclerosis. A recent study from Iceland provides the hitherto several studies have evaluated the natural history of multiple sclerosis natural history data.

Anatomical correlation between first and second attack
An anatomical correlation between the first and second attacks has been described before. One possible explanation for this finding may be an increased recognition of previously experienced symptoms in the individual. However, as the second attack had to show dissemination in space—this being especially difficult for spinal attacks—we believe that the present finding of a 40% increased risk of having the first and second attack in the same anatomical region is rather an underestimation.

Multiple sclerosis natural history data
Several studies have evaluated the natural history of multiple sclerosis. A recent study from Iceland provides the hitherto most favourable description of the disease course. For example, 71% of incident Icelandic cases with a disease duration of 10 to 14 years had an EDSS of <4. The corresponding figure in the present prevalence population was 61%.

The most elaborate and cited study of the natural history of multiple sclerosis is a follow up of cases from 1972 to 1984 at the multiple sclerosis clinic at the University Hospital in London, Middlesex County, Ontario, Canada. One geographically based subgroup, the Middlesex County subgroup, was known to represent 90% of cases identified in a population based survey of this region and was regarded as a cross sectional subset.

Figure 3 shows the distribution of disability status scale (DSS) for the London (Ontario) total population (n = 1098), the Middlesex County subgroup (n = 196), and the EDSS distribution for the Västerbotten prevalence population (n = 322). Only cases examined in 1997 to 1998 in the Västerbotten prevalence population are used for this comparison, thereby compensating for methodological differences such as onset adjusted prevalence. Median EDSS was 4.0 in this population, compared with 3.0 for the remainder, and consequently EDSS was not underestimated. The interpretation of DSS and EDSS differs for some scores but is similar for scores of 3 and 6. Thus disability, as measured by DSS and EDSS, was aggregated into three groups: less than 3, 3 to 5, and 6 and above. The proportion of cases with EDSS/DSS less than 6 was 53% in the Middlesex County subgroup, compared with 61% in the Västerbotten population. This difference, indicating a lesser degree of disability in the present prevalence population, was found despite the fact that data were lacking for the most disabled 10% of cases belonging to the Middlesex County subgroup.

More importantly, the Middlesex County subgroup had a median disease duration of merely 12 years (10 years in the London total population) compared with 16 years in the Västerbotten prevalence population. Figure 4 shows the difference in disease duration between the London total population, the Middlesex County subgroup at final review, and the Västerbotten prevalence population (data for all three available only for RR/SPMS).

Three variables were possibly related to the higher disability despite the shorter disease duration in London, Ontario, compared with Västerbotten. These were as follows.

The proportion of progressive multiple sclerosis from onset
As progressive multiple sclerosis generates most of the accumulated disability in a given multiple sclerosis population, the proportion of cases with this form from the onset will influence disability in that population. In the initial clinical course classification, 33% in the London total population and 30% in the Middlesex County subgroup had...
progressive multiple sclerosis from onset. The clinical course distribution in the London population has been re-evaluated using the same criteria as in the present study, but still 27% (author’s estimate) are classified as PPMS or PRMS. The corresponding figure in the present study is 16% (PPMS and PRMS), which is significantly lower than for the Middlesex County subgroup (p<0.001). The present proportion of cases with progression from onset is in accordance with findings in other elaborate epidemiological studies of multiple sclerosis.

Study population
There is a risk that some selection bias may have occurred in the London multiple sclerosis population as it consists of cases referred to a tertiary referral centre, the London multiple sclerosis clinic. Furthermore, the crude prevalence in the Middlesex County study area (95/10^5) was significantly lower than in Västerbotten (154/10^5, p<0.001). It is likely that the methodology used in the present population will be more likely to identify relatively benign cases.

Time to SPMS conversion
Most people with multiple sclerosis initially have attacks. However, most of the disability, if not all, is generated by disease progression. The proportion of cases converting from RRMS to SPMS by disease duration in the Västerbotten prevalence population is compared with the London total population and Middlesex County subgroup in fig 3. The proportion of RRMS cases free from progression after a long duration of disease appears to be greater in the present sample (only significant for the London total population with a disease duration of ≥26 years when compared with the Västerbotten population with “defined onset” applied; p<0.05). The relatively high proportion of progression-free RRMS cases is also in agreement with the findings in the Göteborg incidence cohort, which was evaluated after 25 years of follow up.

Thus despite a longer disease duration the present prevalence population has less accumulated disability compared with the cross sectional Middlesex County subgroup in the London material. Whether this represents true differences of the multiple sclerosis populations or only reflects different methodology cannot be determined for certain. However, the results from studies of the natural history of multiple sclerosis are strongly dependent on the case retrieval procedure.

Conclusions
We believe that the use of multiple sources for case identification combined with personal follow up is essential to obtain reliable data on the full spectrum of the disease. Using this methodology, one important difference from previous cross sectional epidemiological studies of multiple sclerosis appears to be the better recognition of cases of comparably mild disease. We therefore suggest that multiple sclerosis may be a rather more benign disease than previously recognised.
