Non-invasive brain stimulation for Parkinson’s disease: a systematic review and meta-analysis of the literature

F Fregni, D K Simon, A Wu, A Pascual-Leone

A systematic review and meta-analysis were conducted to quantify the efficacy of transcranial magnetic stimulation (TMS) and electroconvulsive therapy (ECT) for the treatment of motor dysfunction in patients with Parkinson’s disease (PD). Prospective studies which evaluated the effects of either TMS (12 studies) or ECT (five studies) on motor function in PD using the motor subscale of the Unified Parkinson’s Disease Rating Scale (UPDRS) for TMS studies and any continuous measures of motor function in PD for ECT studies were included. The pooled effect size (standardised mean difference between pre-treatment versus post-treatment means) from a random effects model was 0.62 (95% confidence interval: 0.38, 0.85) for TMS treatment and 1.68 (0.79, 2.56) for ECT treatment, and from a fixed effects model was 0.59 (0.39, 0.78) for TMS treatment and 1.55 (1.07, 2.03) for ECT treatment. TMS, across applied stimulation sites and parameters, can exert a significant, albeit modest, positive effect on the motor function of patients with PD. ECT also may exert a significant effect on motor function in PD patients.

Parkinson’s disease (PD) is a progressive neurodegenerative disease that predominantly affects elderly people, and thus it tends to be more prevalent as the population ages. Although the motor symptoms of PD are mainly treated with drugs, the clinical utility of these medications tends to become limited over the years, often due to adverse effects such as dyskinesias (for review, see Olanow et al). Non-pharmacological approaches, such as deep brain stimulation (DBS), are effective in the treatment of PD motor symptoms in selected patients. For instance, in a meta-analysis, Boucai et al showed that functional neurosurgery for PD is effective for improving motor function and dyskinesias, and may even offer advantages over pharmacological approaches. Although recent developments in invasive brain stimulation for PD, such as improvement in the DBS technique and minimally invasive cortical stimulation, have reduced the surgical risks, neurosurgical procedures are still costly and invasive. Therefore, non-invasive forms of brain stimulation are desirable. Electroconvulsive therapy (ECT) and repetitive transcranial magnetic stimulation (rTMS), both types of non-invasive brain stimulation, have been used in PD patients and have been suggested as possible therapeutic tools.

rTMS is a non-invasive, well tolerated technique of brain stimulation based on electromagnetic induction. The effects of rTMS spread from the directly targeted brain region along specific neural connections to distant cortical and subcortical regions. Therefore, it is possible by using rTMS to modulate activity in specific neural networks, using cortical targets as “entry ports”. Several studies have investigated the use of rTMS to treat the motor symptoms of PD patients. The results of these trials are mixed and no conclusion has been reached so far. ECT induces current in the brain by direct transcranial application of a strong current pulse and is associated with the induction of a seizure. The mechanisms of action of ECT are unclear, but several studies have reported that ECT is effective for treating PD patients. However, most of these studies are case reports, and thus, no conclusions have been reached about the utility of ECT in patients with PD.

Therefore, whether non-invasive brain stimulation (ECT or TMS) is effective for treating PD remains unclear; such information would be important to either support or provide evidence against future larger trials of non-invasive brain stimulation for PD. Here, we systematically review studies that examined the effects of TMS or ECT on motor function in PD. We critically assess the heterogeneity of these study results to better understand the factors that may contribute to a better motor outcome following non-invasive brain stimulation.

METHODS

Literature search

The first step of our meta-analysis was a selective literature search for articles published from 1980 to January 2005. We used the following databases: MEDLINE, EMBASE, Cochrane, and SCIELO. In addition, we examined reference lists in systematic reviews and retrieved papers, searched conference abstracts, and talked to clinical experts. To check for unpublished trials, we contacted experts in the field, consulted the CRISP database, and searched for abstracts. Our key search terms were “Parkinson’s disease”, “transcranial magnetic stimulation”, “electroconvulsive therapy”, “brain stimulation”, and “noninvasive brain stimulation”. This strategy

Abbreviations: DBS, deep brain stimulation; ECT, electroconvulsive therapy; PD, Parkinson's disease; rTMS, repetitive transcranial magnetic stimulation; SD, standard deviation; TMS, transcranial magnetic stimulation; UPDRS, Unified Parkinson’s Disease Rating Scale; 95% CI, 95% confidence interval
yielded 127 studies for TMS and PD, and 143 studies for ECT and PD. Using the terms “Parkinson’s disease” with either “brain stimulation” or “noninvasive brain stimulation” yielded no additional studies.

**Selection criteria**
We included prospective studies that evaluated the effects of either TMS or ECT on motor function in PD. We adopted the following inclusion criteria: (i) manuscript written in English, German, Italian, French, Spanish, or Portuguese; (ii) use of TMS or ECT in PD patients; and (iii) motor effects measured using the motor section of the Unified Parkinson’s Disease Rating Scale (UPDRS) for TMS studies or any other continuous clinical scale that evaluated the motor symptoms of PD for ECT studies; we decided to allow other clinical scales, rather than only the UPDRS (for example, the Webster scale was used in the studies by Fall and Andersen) for ECT studies, as most of them were carried out at the beginning of the 1980s and therefore did not report UPDRS scores; (iv) the report had to have been published in a book, journal, proceeding, or indexed abstracts; and (v) the study had to report the mean and standard deviation (SD) of the motor function before and after treatment or provide other statistical parameters that could be used to deduce these values. For studies that met our criteria but did not report these scores, the authors were contacted to provide these data if available. Four out of five consulted authors replied to our request, and three of these four could provide data. For cases where two or more published studies reported overlapping data sets, we chose the study with the largest population. Case reports or series of case reports were excluded.

**Extraction of the outcome measures**
The data were collected using a semi-structured form for each study by one of the authors and checked by another investigator. Discrepancies were resolved by consensus and a third author consulted if necessary. The following variables were extracted: (i) mean and SD of the motor section (part III) of the UPDRS (or other clinical scale for the ECT studies) for baseline and after treatment for the active and placebo group (if the study was sham controlled); (ii) mean and SD for the follow-up period (if these data were available); (iii) study design; (iv) demographic and clinical characteristics (for example, number of patients, age, gender, disease duration); (v) baseline motor UPDRS and Hoehn and Yahr stage; (vi) TMS parameters (frequency, intensity, number of pulses, number of sessions); and (vii) ECT parameters (uni/bilateral, intensity, number of sessions).

For the studies with more than one active group (that is, two different doses of TMS), we considered each group as a separate group (if the study was sham controlled); (ii) mean and SD for the follow-up period (if these data were available); (iii) study design; (iv) demographic and clinical characteristics (for example, number of patients, age, gender, disease duration); (v) baseline motor UPDRS and Hoehn and Yahr stage; (vi) TMS parameters (frequency, intensity, number of pulses, number of sessions); and (vii) ECT parameters (uni/bilateral, intensity, number of sessions).

**Systematic review**
Because the literature on ECT and TMS in PD consists mainly of uncontrolled studies, we included both controlled and uncontrolled studies, and compared the results of the two sets of studies.

**Quantitative analysis**
All our analyses were performed using Stata statistical software, version 8.0 (StataCorp, College Station, TX). For the continuous measures of motor function, we calculated the standardised mean difference (Cohen d) based either on the pre- and post-test values of one group within each study or comparison of the mean changes in pre-treatment to post-treatment UPDRS of the two independent subject groups (sham and active rTMS) in the controlled trials using the means and SDs, or estimated from the graphs (study by Ikeguchi et al\(\text{sd}\)). For the post-treatment value, we used the evaluation that was carried out immediately after the treatment. However, for the trials that also reported an additional post-treatment evaluation within 2 months of the end of treatment (most of them reported a 30 day follow up after the end of treatment), we conducted a separate analysis to evaluate the long term effects of this treatment comparing it to the baseline value (pre-treatment). In the next step, we measured the pooled weighted effect size using random and fixed effects models. The random effect model gives relatively more weight to smaller studies and wider confidence intervals than the fixed effect model and its use has been advocated if there is heterogeneity between studies. Although the test for heterogeneity failed to detect heterogeneity in one of our analyses, we decided to report both values (from random and fixed effects models). As all rTMS trials reported results using the motor UPDRS, we also reported the weighted pooled mean difference to facilitate interpretation of the results.

Heterogeneity was evaluated with the Q statistic. Although some of these tests disclosed a non-significant heterogeneity, this test may have been underpowered due to the small number of studies; therefore, we synthesised the results from individual studies by using the DerSimonian and Laird random effects model to incorporate both within and between study variability and the fixed effect models to compare the results.

As our meta-analysis included small studies and these studies usually have large effect sizes, we evaluated the influence of individual studies, computing the meta-analysis estimates and omitting one study at a time.

As we expected heterogeneity in the effect of treatment between studies, we assessed this source of heterogeneity, in an exploratory manner, performing a meta-regression in which the outcome was the effect size and the covariates were the variables that could have influenced the effect size, such as study design, demographic and clinical characteristics, and TMS parameters. Medication use was not included in this analysis because these data are unavailable for most of these studies. This analysis was not performed for the ECT analysis as only five small studies were included.

We assessed publication bias using the Begg modified funnel plot,\(\text{sd}\) in which the standardised mean difference from each plot was plotted against the standard error.

**RESULTS**
**Studies retrieval**
Using the words “transcranial magnetic stimulation” and “Parkinson’s disease”, we found 127 citations. Five additional citations were found by searching the bibliographies of the retrieved papers and reviews. Therefore, 132 publications were identified and carefully reviewed. Initially, we excluded 110 references for the following reasons: TMS was used to measure other neurophysiological parameters, or the
Publications were reviews or case reports, dealt with other topics, or were in another language. Of the remaining 22 references, 10 were excluded because they used endpoints other than UPDRS to measure improvement in motor function, for instance in reaction time, 13–17 motor evoked potential/silent period, 18 19 and speed of movement, 19 20 or had poor data reporting (the mean and SD for the baseline and post-treatment evaluation did not agree with the p value provided in the study table). Thus 12 studies were selected for the final analysis, of which eight were placebo controlled studies and four uncontrolled studies.

The same process was performed for ECT. Using the words “electroconvulsive therapy” and “Parkinson’s disease”, we found 143 citations. Three additional citations were found by searching the bibliographies of the retrieved papers and reviews. Of the 146 publications identified, we excluded 135 for the following reasons: they were reviews or case reports, dealt with other topics, or were in another language. Of the
remaining 11 references, six were excluded because they were case reports,22–24 did not provide numbers regarding motor outcome,25 26 or were duplicated studies.27 Therefore five studies were selected for the final analysis.

The demographic findings of these studies are summarised in table 1.

Meta-analysis results for TMS trials
Characteristics of the TMS trials are summarised in table 2. Initially, we combined data from the controlled, double blind studies only. Pooling the data of the eight controlled trials, we found a pooled effect size (standardised mean difference between before and after TMS application) from the random effects model of 0.60 (95% confidence interval (95% CI): 0.24, 0.96) and from the fixed effects model of 0.56 (95% CI: 0.30, 0.81) (fig 1). The test for heterogeneity failed to show a significant heterogeneity ($\chi^2 = 15.4, p = 0.052$). These results are similar to the pooled effect size when all studies are included (rather than just double blind studies): the pooled weighted effect size from the random effects model was 0.62 (95% CI: 0.38, 0.85) and from the fixed effects model was 0.59 (95% CI: 0.39, 0.78); no significant heterogeneity was found ($Q_{17} = 24.45, p = 0.11$) (fig 1). This result indicates that the inclusion of uncontrolled studies into our meta-analysis did not alter the outcome of our analysis.

As patients with PD can experience a strong placebo effect, we analysed the effect size on UPDRS change (comparison between before and after treatment) in the sham rTMS group. The method of rTMS placebo varied across the different studies, for example, sham coil,9 28–30 active coil angled at either 45˚28 or 90˚33 and active coil stimulation of occipital area,10 and are not expected to cause motor function impairment other than perhaps through a placebo effect. Therefore for visual assessment. The funnel plot is helpful to identify whether the results are biased due to exclusion of unpublished, negative studies, as the exclusion of these studies results in an asymmetrical funnel plot. This plot shows a slight predominance of data points from large studies below the horizontal line (representing the effect size), thus indicating an opposite effect of publication bias, as these studies have negative results (fig 5). Furthermore, the distribution of the funnel plot is fairly symmetrical, thus suggesting there is no publication bias. Finally, the $p$ value for the Egger test was not significant ($p = 0.12$), therefore indicating that the results of this meta-analysis are not the result of publication bias.

Meta-analysis results for ECT trials
For the meta-analysis of the effects of ECT on motor function in PD patients, only five studies satisfied our inclusion criteria. The characteristics of these studies are described in tables 1 and 5. As only five studies were included in this meta-analysis, we only calculated the pooled effect size using
the random and fixed effects models. This analysis showed a pooled effect size from the random effects model of 1.68 (95% CI: 0.79, 2.57) (fig 2) and from the fixed effects model of 1.55 (95% CI: 1.07, 2.03). The test for heterogeneity confirmed that there was a significant heterogeneity across the studies ($Q_4, \chi^2 = 12.95, p = 0.012$). Because of the small number of studies (five), further analysis, such as meta-regression and Egger’s test, could not be performed. Therefore, we could not systematically assess further heterogeneity and publication bias for this analysis, and thus the results of ECT trials should be interpreted with caution.

**DISCUSSION**

The results of this meta-analysis support the hypothesis that non-invasive brain stimulation (TMS and ECT) can be effective in improving motor symptoms in patients with PD. The analysis of TMS studies showed that this result is consistent across controlled and uncontrolled trials, but the effect is modest. Furthermore, we show evidence against a publication bias or significant heterogeneity, and demonstrate that the result remains robust after excluding any single study. Although we showed that the effects of ECT are significant and, indeed, had a larger effect size when compared to TMS, we could not systematically assess further heterogeneity and publication bias for this analysis, and thus the results of ECT trials should be interpreted with caution.

**Figure 2** Effect sizes representations (filled squares) and their 95% confidence intervals (lines) of the sub-analyses of the meta-analyses. TMS (controlled) indicates the TMS controlled studies only. TMS (ALL) indicates that the uncontrolled and controlled studies were pooled together. TMS (act. v sham) indicates that the sham and active rTMS groups in the controlled trials were compared. Sham only indicates that only the sham group was analysed. TMS (follow-up) indicates that motor scores at the follow up (30 days or more) were compared to baseline. ECT is the pooled effect size for the ECT trials (five studies). A positive effect size indicates that the effect was larger in the post-treatment group, or favoured the active group.

**Figure 3** Effect sizes (standardised mean difference of the scores of the change in motor UPDRS from baseline to after treatment between the active and placebo group) from the random effects model. A positive effect indicates an improvement in motor function in the active group compared to the placebo group. Effect sizes are Cohen $d$ (standardised mean difference), error bars represent the 95% confidence interval.
compared to TMS, the small number of trials limits our ability to draw any definite conclusion about this technique in PD patients.

Negative and positive effect in rTMS trials

Although this meta-analysis shows a favourable effect of TMS on motor function in PD, a positive effect was not observed in every trial. One of the reasons may be the small sample size of these negative studies. In this scenario, the meta-analysis technique is a valuable method to combine the data from small studies in order to provide a conclusion based on an analysis with better power. However, two studies with relatively large sample sizes showed negative results. One explanation for this contradiction might be the interaction of antiparkinson drugs with TMS, as these studies assessed the motor UPDRS after the use of levodopa (“on” state). This medication might mask the effects of TMS due to a ceiling effect. Therefore, assessment of patients in the “off” state may provide a more sensitive measure of the benefit of TMS. An alternative explanation is that the variability of the results stems from the wide range of TMS parameters and patient selection criteria used in these studies, that is, the optimal TMS parameters might vary depending on disease duration and severity. Although the meta-regression results failed to show that TMS parameters could significantly account for the variability across studies in motor improvement, the interaction term (TMS parameters versus patient characteristics) was not analysed because of lack of power for this type of test.

An important consideration is the low number of pulses and intensity in some of these trials, such as the studies of Mally and Stone (30 pulses twice a day, intensity of 20% of motor threshold (MT)) and Shimamoto et al. (60 pulses per day, intensity of 700 V). One can argue that these parameters were too low to induce a biological effect. However, the number of sessions may influence the clinical effects of this technique (for example, in treatment for depression), and therefore the application of rTMS over several sessions in these studies might explain their reported significant effects.

The site of stimulation appears to be critical for rTMS induced motor improvement, and a focal coil, such as a figure-of-eight coil, should provide the greatest precision in targeted stimulation. However, a significant correlation was not found between motor improvement and coil type. For instance five of the seven studies which used circular coils showed a significant motor improvement and the two studies which used figure-of-eight coils did not show any significant motor improvement induced by rTMS. It is likely that the degree of motor improvement depends on interactions between coil type and other parameters, such as frequency, intensity, and stimulation site.

Non-invasive brain stimulation for PD

TMS effects are primarily directed at surface cortical regions. Since the dopaminergic deficiency in PD is localised to the subcortical basal ganglia, the beneficial effects of rTMS on PD motor symptoms are necessarily somewhat indirect. Two pathophysiological mechanisms can be proposed to explain how cortically directed rTMS may improve PD symptoms: either (i) rTMS induces network changes that connect with and positively affect basal ganglia function or (ii) rTMS to cortical sites compensates for systematic abnormal changes in cortical function associated with PD. Indeed, in support of the former mechanism, rTMS might modulate cortical areas, such as the prefrontal cortex and primary motor cortex, which are substantially connected to both the striatum and the subthalamic nucleus via glutamatergic projection, and thus indirectly modulate the release of dopamine in the basal ganglia. Several TMS/functional imaging studies have demonstrated the effects of rTMS on this neural network (although resolution of the images of the basal ganglia in

most of these studies can be limited) and an increase of dopamine in basal ganglia after rTMS of the frontal lobe.43 44

In support of the latter mechanism, functional imaging and TMS studies of PD subjects have demonstrated altered cortical physiology in basal ganglia connected areas such as the supplementary motor area, dorsolateral prefrontal cortex, and primary motor cortex,41 45 46 characterised by excessive corticospinal output at rest and reduced intracortical inhibition. Because a given motor task is associated with suppression of competing motor networks, these cortical changes in PD patients might avoid this suppression and therefore decrease the performance of the motor system, resulting in symptoms such as tonic contractions and rigidity.41 Therefore, rTMS may serve to compensate for the standard basal ganglia model of underactive pallido-thalamo-cortical drive81 71 9 and to modulate cortical excitability to correct for (pseudonormalise) known or suspected abnormalities in cortical excitability associated with PD.19 34

Although these mechanisms of action are based on several studies which have attempted to elucidate the pathophysiology of motor disturbance in PD, they remain unproven, and further investigations are required.

Likewise, the putative mechanism of action of ECT in PD is still unknown. One can conjecture that the effects of ECT on the brain are similar to those following rTMS, but the effects might be amplified as the electric current induced by ECT spreads to a larger area when compared to TMS and induces a greater voltage.47 Although several mechanisms to explain

ECT effects on motor function in PD have been proposed (for example, enhancement of dopaminergic receptors, improvement of depression, disruption of the blood-brain barrier), convincing evidence to support these assumptions is lacking. Finally, the role or confound of the seizure which is always associated with ECT, as opposed to rTMS, remains unclear.

Clinical implications

The results of this meta-analysis suggest that rTMS might be an effective treatment for patients with PD, highlighting the need for additional more definitive clinical studies in PD patients. For a treatment to be considered clinically useful in PD patients, it should fulfill the following criteria: (i) the therapy has to have a long lasting effect (at least hours or days); (ii) the motor improvement has to be clinically meaningful; and (iii) the clinical benefits of a new therapy should outweigh its side effects. Regarding the long lasting effect, only six studies identified in this meta-analysis investigated the long lasting effects of TMS in PD patients. The pooled analysis of these six studies suggested that the effect of one or a few sessions of TMS can last at least 30 days after the end of the treatment. Indeed, a long lasting effect of rTMS has been demonstrated previously in patients with major depression, schizophrenia, and stroke and aphasia. Furthermore, recent studies suggest that even longer term benefits with maintenance TMS treatments are indeed possible and effective for the treatment of depression and PD.

Another important issue is whether the effects of TMS on motor function are clinically relevant, as a statistically significant difference between two treatments (or before and after treatment) does not necessarily equal clinical importance. To analyse this effect, we also report the mean difference (rather than the standardised mean difference) for the TMS studies (as these studies utilised the same scale, that is the motor section of the UPDRS). The pooled mean difference was 5.90 (95% CI: 3.36, 8.44) points on the UPDRS scale (this represents an improvement of more than 20% in motor function compared to the baseline UPDRS). The possibility of a placebo effect must be considered as well. Goetz et al reported a significant placebo effect in 17% of PD patients submitted to a chronic new antiparkinsonian therapy. However, the effect of rTMS on motor UPDRS scores remained significant even for the subset of studies that compared the active rTMS group to a placebo TMS group (fig 3). There also may be differences in the impact of the placebo effect between acute treatment (such as rTMS for one session) and chronic treatment (such as the use of a new drug for several months). For instance, Fregni et al showed no significant motor improvement after a single session of placebo rTMS compared to a levodopa challenge. Furthermore, studies in which several sessions of rTMS were administered, such as those reported by Mally et al and Khedr et al, have larger clinical effects (substantially larger than 20%). Finally, it is possible that optimisation of the TMS treatment protocol and patient selection could result in benefits of greater magnitude. However, it is premature to conclude that long term treatment with TMS might be as effective as treatment with levodopa. Although a retrospective study raised the possibility that rTMS combined with drugs can slow the development of PD, a proper clinical trial with an adequate sample size, methodology, and a long follow up comparing TMS and pharmacological treatment would be desirable.

It is important to consider the side effects of rTMS. In fact, rTMS is a technique associated with only a few, mild adverse events. Analysing the side effects of the studies included in this meta-analyses, four of these studies reported no side effects. Boylan et al reported that one out of 10 patients could not receive repetitive TMS as single pulse motor studies induced an exaggerated startle response and marked worsening of tremor. In the study by Dragasevic et al, although all the patients tolerated the treatment well, the authors reported that four patients complained of a light burning sensation over the scalp during stimulation and

three patients had mild tension headache. Finally, Fregni et al reported mild, benign side effects such as mild headache, neck pain, a mild scalp burning sensation, and increase of salivation, which were more prevalent in the control group compared to the active rTMS group.26

The result of this meta-analysis opens up an avenue for the exploration of electrical stimulation. For example, studies are needed to assess the efficacy of new methods of brain stimulation in PD patients. Transcranial direct current stimulation is one of these therapies which might be valuable in PD. Recent studies have shown that this therapy can induce modulatory effects in the brain cortex similar to those induced by rTMS.27 Cortical (epidermal) stimulation is another therapy which has been investigated for PD. A case report28 and animal study29 showed that epidural motor cortex stimulation may be a good approach to improve symptoms of PD and the benefits may be longer lasting than those following rTMS. In any case, even if the effects of non-invasive rTMS were to prove to be short lived, an rTMS study may be useful to assess the suitability of a given patient for more invasive, cortical stimulation. Extracortical cortical stimulation has the advantage (compared to subdural cortical stimulation) of being minimally invasive (it needs only local anaesthesia to implant the electrodes and is associated with fewer post-operative complications, such as infection and haemorrhage). Future studies are needed to investigate and compare the efficacy of different types of motor cortex stimulation.

Conclusion
This meta-analysis shows that rTMS and ECT can produce statistically significant effects on motor function in PD. Although the results of this TMS meta-analysis are robust and stable (that is, not substantially altered by excluding any single study), its effect size was moderate. For ECT, although there was a relatively large and significant effect size, we considered the low number of studies to be a limiting factor, and therefore avoid any definite conclusions about this method of brain stimulation in PD. Furthermore, the results of this meta-analysis do not answer whether or not non-invasive brain stimulation would have a clinically meaningful benefit in PD patients. However, our findings encourage further larger and carefully designed clinical trials to assess the potential clinical value of rTMS for PD patients.

ACKNOWLEDGEMENTS
The authors would like to thank Steven D Freedman for advice, mentoring, and support; Munir Boodhwani for help with data analysis; and Professor Simin Liu and Emily Levitan, from the Department of Epidemiology of Harvard School of Public Health, for their comments and suggestions on an earlier version of the manuscript.
