Possible transcallosal seizure induction by paired pulse transcranial magnetic stimulation in a patient with frontal lobe epilepsy

Seizure induction by high frequency transcranial magnetic stimulation (TMS) has been reported in normal subjects and by single pulse TMS close to the epileptic focus in patients with epilepsy.1

Case report
We report an 18 year old patient with right frontal lobe epilepsy due to paramedian focal cortical dysplasia (FCD). The patient's usual seizure semiology consisted of a somatosensory aura of the left hand followed by a tonic seizure of the left arm which evolved to a bilateral asymmetrical tonic seizure without loss of consciousness. In the two years preceding the study (see below) he had rare night-time seizures only. His antiepileptic medication consisted of levetiracetam 500 mg, phenobarbital 25 mg, and carbamazepine 1600 mg daily.

During presurgical videoelectroencephalogram (video-EEG) monitoring, interictal EEG revealed right frontotemporal spikes. Ictal EEG revealed seizure patterns with a right frontal onset. Magnetic resonance imaging (MRI) showed FCD in the right superior frontal gyrus extending into the right precentral gyrus (fig 1A). Neurological examination was normal.

Transcranial magnetic stimulation
The patient participated in a TMS study using a protocol described previously2 to evaluate intracortical excitability of both motor cortices (M1). The study was approved by the local ethics committee, and the patient gave written informed consent.

We used a focal 70 mm figure of eight coil connected to two magnetic stimulators via a Bistim module (Magstim Company, Dyfed, UK). Surface electromyography (EMG) was recorded from the contralateral abductor digiti minimi muscle (ADM) of the hand. TMS commenced over the left M1 contra-lateral to the epileptic focus with the coil placed over the M1 hand area. First, motor thresholds (RMT, AMT) and cortical induced silent period at an intensity of 110% RMT were evaluated. Next, paired pulse TMS (conditioning stimulus set at 38% of maximum stimulator output; second stimulus 60% of stimulator output) was started on the left M1 with a train of paired pulses with ISI 2, 10, and 15 ms in a random order.

After 65 stimuli, the patient noticed that his habitual somatosensory aura of the left hand followed by myoclonic jerks of the left forearm (mainly biceps brachii muscle and forearm flexor muscles) was triggered by each stimulus, contralateral to the epileptogenic zone but ipsilateral to the cortical stimulation. The jerks were triggered by both single and paired stimuli at all ISI and rapidly involved both arms. These motor phenomena were different from the typical seizure semiology. EMG recordings of the ADM showed movement artefacts 63–75 ms after the MEP (fig 1B). The TMS was immediately interrupted, which aborted the myoclonus at once.

The TMS data of the left hemisphere showed increased motor thresholds, prolonged cortical induced silent period, markedly decreased intracortical inhibition, and increased facilitation compared with 20 controls (percentiles of the patient's measures within the control group: >99% for ISI 2 and >95% for motor thresholds and ISI 15, >90% for ISI 10, and >85% for ISI 3).

After the TMS experiment, the patient was again free of daytime seizures until the last follow up visit six months later.

Transcallosal seizure induction by paired pulse TMS
In patients with epilepsy, all reported cases of seizure induction by TMS have occurred during ipsilateral stimulation and near to the epileptic focus. Therefore, it has been assumed that direct stimulation of the epileptogenic tissue was required to trigger a seizure.3 We used a focal coil placed over the left M1 hand area more than 5 cm away from the midline. Thus, it is unlikely that the right hemisphere FCD participated in seizure induction. However, the present patient was stimulated directly, and we assume that an indirect transcallosal activation of the epileptogenic zone provoked the aura. The latency of 65–75 ms of the myoclonic jerks after the MEP may reflect a polysynaptic pathway from a transcallosal connection of both M1. It is still not clear whether involvement of additional cortical areas such as the ipsilateral and contralateral sensory cortices or basal ganglia contributed to the seizure provoked. Despite the patient's statement that the jerks were not volitional, this cannot be completely ruled out. The preceding somatosensory aura, however, represented his typical seizure semiology. We hypothesise that transcallosal activation of the epileptic focus was promoted by the increased excitability of M1, which was due to the underlying FCD. This, in turn, led to the aura and peri-ictal changes in M1 excitability facilitating TMS driven myoclonic jerking. It has been previously reported that FCD is intrinsically epileptogenic and promotes reflex seizures.4

There is a possibility that ipsilateral pathways of movement activation could underlie our observations. In a child with extensive cortical dysplasia, TMS of the unaffected hemisphere evoked MEPs in both ADM muscles implying bilateral corticospinal connections from one cortex.5 Histological studies on severe brain damage in early development have revealed collateral sprouting into denervated areas of cortex or spinal cord.6 Ipsilateral activation under maximum muscle contraction has been observed in healthy volunteers and in patients with acute stroke.7 Our patient, however, presumably had congenital but circumscribed FCD, no motor deficits, and was investigated at rest. This and the fact that his habitual somatosensory aura occurred before the myoclonic jerks strongly argue against the activation of ipsilateral corticospinal tracts. Activation of a silent mirror focus in the left hemisphere with subsequent spread to the right is also unlikely because exclusively right sided ictal and interictal epileptiform discharges were recorded during the video-EEG monitoring.

Changes in motor cortex excitability
Our patient's higher motor thresholds compared with controls are very likely due to his ion channel blocking anticonvulsant medication.8

Figure 1 (A) Axial T2-weighted magnetic resonance imaging (MRI) scan (fluid attenuated inversion recovery [FLAIR]) of the patient's brain. T2 prolongation and blurring of grey-white junction represents focal cortical dysplasia of 1 × 1 cm (see circle) located in the right superior frontal sulcus (extending to the right motor cortex, seen in further MRI slices). (B) Examples of motor evoked potentials (MEPs) from the right abductor digiti minimi muscle (ADM) during transcranial magnetic stimulation of the left hemisphere at different interstimulus intervals (ISI) and after unconditioned test stimulus. The patient showed stimulus triggered myoclonic jerks of both hands and forearms leading to movement artefacts in the ADM recordings.
The loss of intracortical inhibition and increased intracortical facilitation in the left hemisphere contralateral to the epileptogenic zone may reflect synaptic reorganisation of the ipsilesional and contralesional motor cortices. These distant functional cortical changes associated with malformations of cortical development have also been described previously. The prolongation of the cortical induced silent period seen in the present patient may be independent of the phenobarbital intake and confirms similar findings from previous studies as a remote effect of FCD on the motor cortex in untreated patients with cortical dysgenesis.

**Conclusion**

Unilateral epileptic FCD involving M1 can induce complex bilateral alteration of motor cortex excitability resulting in a net increase of excitability. In such cases, transcallosal seizure induction appears to be possible with paired pulse TMS using a focal coil away from the epileptic focus.

**Hashimoto's encephalopathy: steroid resistance and response to intravenous immunoglobulins**

Hashimoto's encephalopathy is a steroid responsive disorder characterised by high titres of anti-thyroid antibodies. The original description of this condition was in an established case of Hashimoto's thyroiditis where the patient developed focal neurological deficits and coma. Clinical presentation includes episodic confusion, myoclonus, seizures, and stroke-like episodes. Females are more affected than males (3:6:1), with a mean age of onset of 41 years. The hallmark of HE is its response to steroids, usually improving within a few hours to days. The titres of anti-thyroid antibodies may be variable, and the disorder, but the majority of patients are euthyroid. Although steroid responsiveness is the rule, additional immunosuppressive therapy may be required. The role of azathioprine and cyclophosphamide has been controversial. Although reversible MRI abnormalities have been described in HE, neuroimaging (except for isolated patchy uptake by isotope scans) is usually normal in most cases. Cerebral angiography has been found to be normal in several cases of HE, unlike in many other cerebral vasculitides.

Several pathophysiological hypotheses have been suggested for HE. The initial report of HE suggested a vascular aetiology followed by localised cerebral oedema as a possible mechanism. Some authors suggest that the form of HE may be a manifestation of CSF thyroid autoantibodies may react with a putative CNS antigen and form immune complexes. The immunopathological basis of this syndrome has been compared to a re-aggregating form of autoimmune encephalomyelitis. Although reversible MRI findings have been described in HE, neuroimaging (except for isolated patchy uptake by isotope scans) is usually normal in most cases. Cerebral angiography has been found to be normal in several cases of HE, unlike in many other cerebral vasculitides.

Thyroid autoantibodies can co-exist with several other forms of autoimmune encephalomyelitis, but the normal MRI scan, the initial dramatic response to steroids, and negative autoantibodies for most other common vasculitides, tends to favour the diagnosis of HE in our case. Steroid responsive encephalopathy associated with Hashimoto's thyroiditis is an alternative proposed diagnosis for this condition, but the vast majority of cases have normal thyroid function, leaving “Hashimoto's encephalopathy” as a universally accepted term. A recent literature review of patients with encephalopathy and anti-thyroid antibodies suggests that the combination of encephalopathy, high serum anti-thyroid antibody concentrations, and
responsiveness to glucocorticoid therapy seems unlikely to be due to chance. The initial meningo-encephalitis type presentation of our patient in 1987 was probably the first manifestation of HE in view of clinical findings and laboratory data (Mild CSF pleocytosis is not unusual in HE.) There was a delay of 14 years before the diagnosis was first established, in spite of several hospital admissions. The initial relapses after diagnosis responded well to steroids, confirming the diagnosis of HE. Whether the current episode was precipitated by the sudden withdrawal of oral steroids or the chest infection itself, for which they were prescribed, is unclear.

Our patient illustrates the possibility of steroid resistance in an established case of HE and the need to consider further immunomodulatory therapy. Intravenous immunoglobulins are a safe, convenient, and effective treatment in such circumstances.

Spontaneous lobar haemorrhage in CADASIL

CADASIL is an autosomal dominant form of arteriopathy, primarily affecting cerebral vessels, and predominantly caused by point mutations in the Notch3 gene on the short arm of chromosome 19. Affected individuals develop subcortical strokes and cognitive deficits in their 30s and 60s. Brain magnetic resonance imaging (MRI) shows large areas of leuкоencephalopathy and multiple subcortical lacunar infarcts. Small arteries and capillaries are characterised histologically by non-atherosclerotic, non-amyloid angiopathy with accumulation of granular osmiophilic material (GOM) within the smooth muscle cell basement membranes and extracellular matrix. While CADASIL is considered a primarily ischaemic form of vascular dementia, microhaemorrhages have recently been reported in 31% of symptomatic Notch3 mutation carriers, suggesting that structural fragility of the arterial walls may lead to leaking of haem products. Lobar haemorrhage in the absence of other risk factors for haemorrhage has previously been reported in one patient with CADASIL. Here we report a second case.

Case report
A 56 year old man who had been diagnosed with multiple sclerosis six years earlier was admitted to the hospital with an acute change in mental state. He had collapsed at home and was unresponsive when rescue arrived. In the emergency room he had a depressed level of consciousness and difficulty following commands, with paucity of speech, dysarthria, and hypophonia. There was no evidence of head trauma. His blood pressure was 100/63 mm Hg and his temperature was 36.1°C. Past medical history included chronic obstructive pulmonary disease, prostate resection for prostate cancer, and a history of nicotine and alcohol dependence. He had no history of hypertension, diabetes mellitus, or coagulopathy. His drug treatment included ipratropium, ranitidine, methyprednisolone, and albuterol. His mother, now deceased, had been diagnosed as having multiple sclerosis and had migraines with aura, stroke-like symptoms, and dementia. He had eight siblings, three with head injuries, and one with recent transient ischaemic events.

Computed tomography (CT) of the head in the emergency department showed an area of high attenuation in the right frontal lobe consistent with an acute intraparenchymal haemorrhage (fig 1A). There was no evidence of trauma on head CT. Gradient echo MRI sequences of the brain done on hospital day 2 showed a 2×2.5 cm area of haemorrhage in
the superior-anterior aspect of the right fronto lobe white matter as well as a microhaemorrhage in the right parietal region (fig 1B). The area of haemorrhage was hypointense on T2 (fig 1C) and iso-
intense on T1 weighted sequences (fig 1D), consistent with acute haemorrhage. There was no MRI evidence of a cavernous haem-
angiomata or arteriovenous malformation, or tumour. Magnetic resonance angiography was not done.

A brain biopsy of the right fronto lobe done on the seventh hospital day showed degeneration of small and medium sized arteries. Vessel walls were thickened and amal-
nised in the grey matter, white matter, and meninges. PAS staining was positive and the muscular coat of the large vessels revealed degenerative changes. Electron microscopy showed the granular osmiophilic material characteristic of CADASIL. Notch3 gene test-
ning revealed a R133C mutation in exon 4, consistent with the diagnosis of CADASIL. The patient remained normotensive through-
out his hospital stay. On the fifth hospital day, the patient returned to the ward. On the sixth hospital day he developed aspiration pneumonia requiring mechanical ventilation. He died eight days later as a result of this pneumonia.

Comment

This is the second report of spontaneous cerebral haemorrhage in a patient with CADASIL. In 1977, Sourander and Wallinder reported a 29 year old man with hereditary multi-infarct dementia on anticoagulants, with a large haemorrhage in the right hemi-
sphere. This family was thought to be one of the first with CADASIL; however, recent testing for mutations in the family has not confirmed that diagnosis. In 1992, Baudrimont et al reported a case of massive left cerebral haematomata involving the cau-
date nucleus, internal capsule, and thalamus, in a 40 year old normotensive woman who was a member of a large CADASIL family. She had no known history of other risk factors for haemorrhage.

The index patient in this report had no evidence of coagulopathy and no history of previous hypertension, cerebral haemorrhage, or anticoagulant therapy. The patient could have experienced a haemorrhagic con-
tusion related to a closed head injury during his unobserved fall before admission, but there was no evidence of trauma on physical examination or on head CT. On MRI there was no evidence of a cavernous haem-
angiomata, arteriovenous malformation, or neoplasm. Necropsy was not carried out.

Ultrastructural analysis of small arteries in human postmortem brain and skin in patients with CADASIL shows breakdown of the arterial wall cytoarchitecture, which may help explain the propensity for microhaemor-
rhages. The first notch3 transgenic mouse shows early widening of the subependymal and intra-smooth-muscle spaces in the vascu-
lar smooth muscle cells, denoting weakening of the arterial wall and increasing susceptibility to micro- and macrohaemor-
rhages.7

This case report supports the growing evidence for both ischaemia and haemorrhage in a variety of small artery diseases includ-
ing amyloid angiopathy and CADASIL.8 Clinical examination must consider the possibility of haemorrhage when evaluating new events and deciding on treatment for stroke preven-
tion in patients with CADASIL.

Urinary retention caused by a small cortical infarction

The cortical representation of micturition is speculated to reside in the medial frontal lobes.1 2 Lesion pathology, however, varies from acute stroke to a neoplasm, and there is no necessarily a small, distinct lesion.3 We report a case of urinary retention in which the main presenting symptom is thought to have been caused by a small cortical infarction.

Case report

One morning, a 66 year old, right-handed man had difficulty urinating. He had no history of voiding difficulty, diabetes mellit-
es, or urinary tract infection. On the lower urinary tract neurological disease. Digital rectal examina-
tion and ultrasonography of the prostate detected no enlargement. Urinalysis showed no haematuria or pyuria. He was not taking any medications that cause voiding dysfunc-
tion. There was no urinary incontinence, but he had difficulty in voiding even though he felt the bladder was full. At that time, he also had difficulty in lifting his left arm and leg and so was brought to a hospital. Neurological examination in the emergency room found no weakness, and he was sent home. Later, he experienced urinary retention and visited the emergency room again. His post void residual urine volume was 350 ml, and an urinary catheter was inserted. At that time the patient was alert, and his cranial nerves were intact. Limb muscle strength was normal. Sensory examination was unremarkable, and his plantar reflexes were normal in all four limbs. Tandem gait and standing on one foot were difficult. He had normal bladder sensation but difficulty in urinating. Drip infusion pyelography revealed no abnormality in the morphology of the bladder or the form of the bladder. Filling cystometry showed stable detrusor with normal bladder sensation, whereas acountactile detrusor was noted in the voided phase. He could void normally with strain, having a flow rate of 5.0 ml/s and a voided volume of 135 ml. Diffusion weighted MRI, performed on the day of onset, showed a small, distinct, high intensity signal, and T1 weighted imaging showed a low signal in the posterior subcortical of the anterior cingulate gyrus, indicative of an infarct in the acute stage (fig 1A and C). No definitive infarct was observed elsewhere. MR angiography showed no stenosis of the intracranial vessels. An electrocardiogram was normal. Transthoracic echocardiograms showed no abnormal find-
ings. The urinary catheter was withdrawn 3 days after admission. Tandem reflexes were normal, but subsequent difficulty with urination. His gait returned to normal about the same time.

Discussion

In the acute stage of a cerebral vascular accident, the presenting symptom often is urinary retention due to detrusor areflexia,4 but patients who have this problem usually have a major stroke with severe neurological deficits.

To the best of our knowledge, this is the first report in the English literature of urinary retention, although temporary, caused by a small cortical infarct as shown by diffusion weighted MRI.

Various cortical areas are activated during voiding because a network of brain regions is necessary for voiding modulation.5 The location of the primary cortical center for voiding and storage are speculated to be separate, the former being at the para-central lobule.6 A PET study found normal micturi-
tion to be associated with activation of the middle frontal gyrus, superior frontal gyrus, superior precentral gyrus, thalamus, and the caudal part of the anterior cingulate gyrus in the left hemisphere.6 Another recent PET study showed that increased brain activity related to increasing bladder volume was located in the bilaterally mid-cingulate cor-
tex, while that related to decreased urge to
void was bilaterally in a different portion of the mid-cingulate gyrus.¹

Although the infarct in our patient was located in the caudal part of the anterior cingulate gyrus, it was on the right side, near the region activated in the PET study.² SPECT showed increased blood flow in the right medial frontal area, indicative that urinary retention was due to "decreased urge to void," and decreased flow in the right medial parietal lobe, which might explain the gait disturbance, in light of the essentially normal sensory examination. Unfortunately, a PET scan was not available in our hospital (Kameda Medical Center). Because there has been no report of an isolated lesion of the cingulate gyrus causing hemiparesis, these brain imaging studies indicate that the left hemiparesis, which disappeared within a half day of onset, could have been due to a transient ischemic attack. Urinary symptoms disappeared 3 days after admission, probably because the cortical neuron network compensated by providing a functional alternative to the lesion damaged by the infarct. This is similar to the condition of urinary incontinence after cerebral infarction, as is well documented. The laterality of the lesion in this patient differs from that in a previous PET study³ which showed bilateral activation in the cingulate gyrus. Because this report cites only a single case, its applicability is limited. Additional lesion studies of patients with micturition disturbance due to small cortical infarcts should help to identify the anatomical cerebral structures involved in voiding.

BOOK REVIEW
Neuropsychiatry and behavioural neurology explained

This is an ambitious project for a single author; the whole of neuropsychiatry explained using an up to date, evidence based review of the literature, and in a format that is designed to be attractive to read. There are numerous figures, boxes, lists with bullet points, and "clinical pointers" to break up the text.

Although aimed particularly at liaison and old age psychiatrists, this book will have wide appeal and be of interest to neurologists. They will be able to quickly access clinically relevant discussion of the neuropsychiatric sequelae of common neurological disorders. The core sections of the book, on dementia and delirium, neuropsychiatric treatments, and the psychiatric complications of neurological diseases, are excellent. The discussion is practical and to the point. The reader is not stifled with references strewn in the text. They must therefore have confidence in the assertions of the author; I am confident that we are being offered accurate information. But at times the style feels a little pedantic; for example, those of us who dared to believe that alcohol may cause depression are put firmly in our place. Another quibble I have is the value of some of the lists/classifications which were of uncertain provenance. We are, for example, given lists suggesting difference aetiologies for chorea versus athetosis, but some would be sceptical of the value in splitting choreathetosis. Many classifications are based on neuroanatomical models of neuropsychiatry that need to be treated with caution.

The book strays into biological psychiatry, and a later section is devoted to understanding how neurological disorders result in neuropsychiatric symptoms, but this does cause a problem because some of the discussion of the neuropsychiatric sequelae of a particular disorder may not be found in the index chapter on that disorder, but in this later section. For example, the only discussion of suicide following head injury in the chapter on head injury is a single misleading sentence indicating that suicide accounts for 10% of head injury deaths. Yet, easily missed, 300 pages later, in the chapter on the neurological origins of suicide, is a more complete account of the relationship.

Overall, however, this book is a significant achievement. A large amount of material has been made readily accessible. There are no lacunae and the length of discussion of each disorder is proportionate to its importance.

The book is to be trusted and recommended. One interesting innovation is a list of support groups and useful websites in the appendix. Neuropsychiatrists and psychiatrists and their trainees have good reason to buy this book.
