Long term results of unilateral posteroventral pallidotomy for antipsychotic drug induced tardive dyskinesia

Tardive dyskinesia (TD) is a well known side effect of neuroleptic drug treatment, and may coexist with tardive dystonia.1 It can be treated with several drugs, although they rarely lead to a complete removal of symptoms. The main treatment of TD consists of gradual neuroleptic drug dose reduction and where possible complete withdrawal.2 Nevertheless, in 40% of TD cases, symptoms do not disappear within 5 years of drug withdrawal. Wang et al first described a pallidotomy as a treatment modality for TD.3 In severe cases of TD and dystonia, this can lead to very significant deterioration of abnormal movements and pronounced improvement in function and quality of life.4

PATIENT AND METHODS

We report a 51 year old, chronically hospita- lised man with a 29 year history of schizophrenia. During this period, he was treated successfully for his psychotic symptoms with depot haloperidol and cisisoridol. In 1993, he developed TD. Initially it consisted of an involuntary tic (myoclonus-like movements of the orofacial muscles), referred to in the literature asTD.5 Both hands showed dystonic and myoclonic movements, the left hand less pronounced than the right, and there was severe acatisia. Haloperidol treatment was discontinued and symptoms of psychosis relapsed. Other medications tried included biperiden (6 mg/day), sulpiride (400 mg/day), amantadine (200 mg/day), decetimide (1.5 mg/day), oxazepam (50 mg/ day), and clonazepam (1.5 mg/day). Treatment with clozapine (up to 400 mg/ day) and valproate (600 mg/day) improved the psychosis and the TD temporarily, but symptoms returned and became severely devastating and invalidating, because TD progressed to involve choreo-atheothic move- ments, most pronounced on the right side of the body and the midline. The patient also developed choreo-atheothic movements of the jaws, tongue, lips, neck, and upper chest muscles, leading to improper and irregular breathing, involuntary grinding, production of uncontrollable noises, and frequent periods of pain in the chest. There was dysarthria, but no abnormal swallowing. He could walk, but only in a very dyskinetik manner. Socially he was totally isolated.

Huntington’s disease and Wilson’s disease were excluded. The pre-operative Unified Dystonia Rating Scale (UDRS) Revised score was 24. Dyskenesia and dystonia, as scored by the Unified Parkinson’s Disease Rating Scale (UPDRS) were rated as 4 for both.

Owing to the unsuccessful medical treat- ment, and onset of a rapid deterioration in dyskinetic symptoms in the right side of the body, we decided on left sided posteroventral pallidotomy. In July 1999, the patient underwent surgery. Because of thoracic kyphosis, he could not be placed in a head coil or neck quad. We therefore obtained a pre-operative CT scan for “indivi- dual targeting”. The coordinates of a target in the posteroventral globus pallidus (GP) were established (2 mm in front of the mid-posteroventral pallidus (AC-PC), 5 mm below the AC-PC and 21 mm lateral of the AC-PC (head width 16 cm, third ventricle width 6 mm, AC-PC 25 mm long)). Five lesions were made at 8, 6, 4, and 2 mm, and on target at 82° for 60 s. As this did not result in a satisfying improvement of dyskinesia, a 2.0 mm diameter unipolar radiofrequency electrode (Fisher TCU 003) was inserted 2 mm lateral to the first target point. A second series of lesions was performed as above, which resulted in a complete disappear- ance of abnormal movements.

Post-operatively, no complications were observed. Involuntary grinding was reduced by 95%. The patient was discharged from hospital 7 days after the operation, after withdrawal of phenytoin, dexamethason, and ciprofloxacin. The post-operative UDRS score was 2, and dyskinesia measured with the UPDRS was 0.

A post-operative CT scan of the brain showed a lesion centred 23 mm lateral of the midline in the calculated target point in the left GPi. One year after this pallidotomy, the patient was functioning very well. He was very content with the nearly complete abolition of dyskinesia and dystonia. His UDRS and UPDRS scores remain at 2 and 0 respectively.

DISCUSSION

In this case report, we describe the outcome of posteroventral pallidotomy in a patient with drug induced TD. As more experience is gained,6 posteroventral pallidotomy, a pro- cedure with documented effects on parki- sonian dyskinesias and dystonia, seems to be an effective treatment to improve or abolish symptoms of this movement disorder. The effect is not only apparent immediately and during the first months after pallidotomy, but as is shown in this patient can be maintained for long period of time.

Gpi target localisation was based on CT as an MRI was anatomically not possible. This would have been a good case for microelec- trode recording, which at the time was not available at our hospital. Instead, we overlaid two CT images, taken parallel to the AC-PC line to enhance contrast, and compared them with the concurrent Schaltenbrand atlas page. This indicated that in the second, effective, series of lesions we targeted the Gpi close to the border of the Gpe. In Parkinson’s disease, very often a very small lesion in the Gpi can immediately be very success- ful; however in this our patient such a “parkinson Gpi lesion” had no immediate visible effect. This does not exclude the possibility that over a longer period of time positive postoperative results could have evolved, as is often observed in patients with dystonia after pallidal stimulation or pallidotomy.

In our opinion, compared with pallido- tomyes in Parkinson’s disease, the target for TD and dystonia could be anatomically slightly different—that is, more lateral in the posteroventral GP perhaps because of different activity of the GPi. More study into this pathology is needed.

An Iranian family with congenital myasthenic syndrome caused by a novel acetylcholine receptor mutation (CHRNE K171X)

Acetylcholine receptor (AChR) deficiency is the most common form of congenital myasthenic syndrome (CMS). Most AChR deficiencies are caused by mutations in the coding region of the AChR epsilon subunit.1 We report an Iranian Muslim family from the province of Eastern Azerbaijan (Maraghê) in which three of five offspring of consanguineous parents had early onset CMS arising from a newly described mutation in the epsilon subunit of the AChR; this mutation

Most AChR deficiencies are caused by mutations in the coding region of the AChR epsilon subunit.1 We report an Iranian Muslim family from the province of Eastern Azerbaijan (Maraghê) in which three of five offspring of consanguineous parents had early onset CMS arising from a newly described mutation in the epsilon subunit of the AChR; this mutation
has been identified homozygously in all the three sibs. This is the first report of an AChR epsilon subunit mutation in Iran.

**Case presentation**

The affected brother (case 1) was 23 years old and the affected sisters were 19 (case 2) and 16 (case 3) years old. The unaffected brother was 21 and the healthy sister was 13 years old. There was no history of miscarriage or infant mortality in the family, although, according to verbal accounts from the mother, fetal movements were decreased in all the affected sibs and case 1 had a difficult labour. The clinical diagnosis of CMS in this family had been made first in 1996. All cases presented with neonatal hypotonia, re- gurgitation, ptosis (case 1 developed ptosis at the age of 6 months), and delayed motor milestones. The course of the disease had been slowly progressive, transiently exacerbated by stress. Generalised weakness was more severe in the afternoons. Treatment with prednisone for 1 year yielded no improvement. There was positive response to pyridostigmine bromide (Mestinon) and the required doses had gradually been increased. There were no other affected relatives in the family.

On clinical examination, all patients were ambulant, although with limited walking distance. There was bilateral ptosis and limited eye movements. The bulbar muscles were also involved, manifesting as nasal speech (more severe in case 1), chewing problems (in cases 1 and 3), swallowing difficulties, and bilateral facial weakness. Pupillary response to light was normal. Muscle involvement was predominantly proximal. Cases 1 and 3 had a waddling gait, especially in the afternoons. Deep tendon reflexes were normal. There was no muscle wasting, scapulae alatae, scoliosis, or respiratory distress. No hospitalisations for respiratory problems were reported. Case 1 had left elbow hyperlaxity and case 3 also revealed severe bilateral elbow hyperlaxity (more severe on the left side). Case 3 had mild flexion contracture of her left knee.

**Electromyography of nasalis muscles showed flexion contracture of her left knee.**

Severe bilateral elbow hyperlaxity (more severe in the afternoons). Deep tendon reflexes were normal. There was no muscle wasting, scapulae alatae, scoliosis, or respiratory distress. No hospitalisations for respiratory problems were reported. Case 1 had left elbow hyperlaxity and case 3 also revealed severe bilateral elbow hyperlaxity (more severe on the left side). Case 3 had mild flexion contracture of her left knee.

Muscle enzymes were normal. Electromyography of nasalis muscles showed decrements (60%, 53%, and 35% in cases 1, 2, and 3, respectively) in response to low frequency repetitive nerve stimulation. Anti-AChR antibodies were negative in all affected sibs.

**Genetic analysis**

All 12 exons, adjacent intronic regions, and the promoter region of the AChR epsilon subunit gene (CHRNA, GenBank accession number AF105999/gi4580858) were amplified by PCR. PCR amplified fragments were purified with the QiAquick Gel Extraction kit (Macherey-Nagel, Düren, Germany) and sequenced with an Applied Biosystems model 3100 Avant DNA sequencer and fluorescence labelled dyeode terminators (Perkin-Elmer, Foster City, CA, USA).

Screening for mutation K171X of the CHRNA gene was performed by restriction digest of PCR products in the patients and the healthy siblings. A 304 bp fragment containing exon 6 was amplified by PCR from genomic DNA using primers 5’-AGGTACAGATGGGAACAGAG-3’ and 5’-CTCTGACCCCGTCTAGAAGCG-3’ and 5’-TCTGGACCCCGTCTAGAAGCG-3’ and 5’-CTCTGACCCCGTCTAGAAGCG-3’. A BfI digest yields 218, 71, and 15 bp fragments for the wild type allele. The mutation K171X introduces a new BfI restriction site, therefore resulting in fragments of 153, 71, 65, and 15 bp in length (fig 1).

Analysis of the CHRNA gene revealed a homozygous nonsense mutation K171X (511A>T) in all three affected siblings. The two healthy sibs did not carry this mutation. DNA of the parents was available for genetic analysis. The mutation has not been previously described in CMS patients with AChR epsilon mutations, one of our cases (case 1) had mild flexion contracture of her left knee, although, in contrast to patients with RAPSN mutations, no cases of ours had arthropathy multiplex congenita. A distinguishing feature in cases 1 and 3 was the presence of asymmetric elbow hyperlaxity. Joint laxity has not been previously reported in any type of CMS; however, it can be seen in some congenital myopathies. We postulate that fetal hypotonia in the presence of intrauterine biomechanical forces might have influenced the normal modelling of the elbow joint.

It seems that the incidence of CMS in Iran is similar to that in other countries. Recognition of differing features of CMS could help establish a definite genetic diagnosis and help implement appropriate measures.

Transient ischaemic attack with trigeminal autonomic symptoms

Trigeminal autonomic cephalalgiea present with excruciating headaches and accompanying autonomic features such as ipsilateral lachrymation, rhinorrhoea, and eyelid ptosis. For clinical purposes, these headaches are subclassified into cluster headaches, paroxysmal hemicranias, and the SUNCT syndrome (sudden unilateral neuralgiform headache with conjunctival injection and tearing), of which the paroxysmal hemicranias subtypes such as the acute and chronic hemicranias are indomethacin responsive. Neuroimaging is often normal in trigeminal autonomic cephalalgias; nevertheless MRI should be considered, as there are associations between trigeminal autonomic cephalalgia and multiple sclerosis, lateral medullary infarction, pontine tumours, basilar aneurysms, and other posterior fossa lesions. We present an unusual case of recurrent transient ischaemic attacks (TIA) with symptoms reminiscent of a trigeminal autonomic cephalalgia which ceased after a ponto-mesencephalic infarct.

Case report

A 65 year old women was admitted with a three day history of stereotyped neurological episodes. These were characterised by a burning sensation in the left side of face, congestion of the left eye, lachrymation from the left eye, watery discharge from the left nostril, slurring of speech, and difficulty in walking. These episodes were not accompanied by headache. Each episode lasted for around 30 minutes and occurred three or four times a day. On examination, there were no focal neurological deficits. In hospital, she had four more episodes. As she had a left mature cataract (fig 1), the possibility of glaucoma induced by lens rupture was considered and ruled out. Computed tomography of the brain was unremarkable. The possibilities considered were a vertebro-basilar syndrome; or a trigeminal autonomic cephalalgia. As she had additional neurological symptoms, a TIA was considered more likely than trigeminal autonomic cephalalgia, and she was started on aspirin and intravenous heparin. Indomethacin was begun at 75 mg/day but had to be discontinued after a single dose because of gastric distress. Two days later, her episodic symptoms disappeared; however, she now complained of persistent right side weakness and difficulty in walking. On examination, she had a new left sided Horner’s syndrome, right upper motor neurone facial palsy, and right upper limb weakness. Deep tendon reflexes were brisker on the right than on the left. Magnetic resonance imaging of the brain at this time showed an acute left pontomesencephalic infarct (fig 2).

(one week after the onset of symptoms) showed an acute infarct at the left pontomesencephalic junction (fig 2). At follow up 10 days later, her gait had improved. Her episodic symptoms had disappeared.

Comment

Cranio-facial autonomic symptoms such as ipsilateral lachrymation, rhinorrhoea, conjunctival congestion, ptosis, or eyelid oedema are the sine qua non of trigeminal autonomic cephalalgia. It is thought that activation of the trigeminal afferent system generates pain, and co-activation of the VLth nerve efferent parasympathetic pathway produces the autonomic manifestations such as ipsilateral lachrymation and rhinorrhoea. A mechanism analogous to this can be evoked to explain our patient’s symptoms. She had an ischaemic stroke in the ponto-mesencephalic junction. Ischaemia in this region could involve the trigeminal main sensory and mesencephalic nuclei, resulting in facial dysaesthesia comparable to ischaemic nerve pain. In contrast to the “boring” intense pain of body temperature when the patient has been lying on one ear, many stroke patients are hemiparetic or hemiparetic and therefore may lie on one ear. The aim of our study was to investigate the error in tympanic temperature measurements in patients who have had a stroke and have been lying on one ear in this way.

For this observational study we included patients who had had an ischaemic or haemorrhagic stroke and were admitted to the stroke unit of a university medical centre or to the stroke rehabilitation unit of an affiliated nursing home, both in an urban area. Exclusion criteria were inability to lie on one ear and absence of a rectal cavity. We used the NIH stroke scale (NIHSS) to assess stroke severity.4 No follow up was conducted.

Tympanic temperature was measured in both ears after the patient had been lying in one ear of choice for at least 15 minutes (first measurement). The measurements were carried out in patients on waking in the morning or after an afternoon nap. The ear the patient had been lying on and the other ear will be further referred to as the lower ear and the upper ear, respectively. The second measurement was conducted by a different investigator—who was not aware of the results of the first measurement—approximately 10 minutes after the patient had no longer been lying on one ear, and consisted of tympanic and rectal temperature measurements.

To assess reliability we computed the difference between lower and upper ear temperature in consecutive tympanic measurements and analysed this difference graphically, as described by Bland and Altman.5 Validity was assessed by comparing the mean

Tympanic measurement of body temperature in stroke patients “turned on its ear”

Body temperature is an important prognostic factor in acute stroke, and it is a marker of life threatening infections such as pneumonia.6 In clinical practice rectal temperature is regarded as a valid and reliable indicator of body temperature, but in the past 15 years tympanic infrared thermometers have been introduced into widespread clinical use. Tympanic temperature measurement is easier, faster, and less invasive than rectal measurement. However, concerns remain about the reliability and validity of this method.2

The product manual of the tympanic thermometer warns against overestimation of body temperature when the patient has been lying on one ear. Many stroke patients are hemiparetic or hemiparetic and therefore may lie on one ear. The aim of our study was to investigate the error in tympanic temperature measurements in patients who have had a stroke and have been lying on one ear in this way.

For this observational study we included patients who had had an ischaemic or haemorrhagic stroke and were admitted to the stroke unit of a university medical centre or to the stroke rehabilitation unit of an affiliated nursing home, both in an urban area. Exclusion criteria were inability to lie on one ear and absence of a rectal cavity. We used the NIH stroke scale (NIHSS) to assess stroke severity.4 No follow up was conducted.

To assess reliability we computed the difference between lower and upper ear temperature in consecutive tympanic measurements and analysed this difference graphically, as described by Bland and Altman.5 Validity was assessed by comparing the mean

Figure 1 Congestion of the left eye during an acute attack. The patient gave written consent for this photograph to be reproduced.

Figure 2 T2 Weighted magnetic resonance image showing an acute left pontomesencephalic infarct.
The mean difference between the tympanic temperatures with mean rectal temperature:

We studied 30 patients (nine male, 21 female). Their mean age was 69.3 years, and their median NIHSS score was 11, ranging from 0 to 38. The mean of the first tympanic temperature taken from the lower ear was 37.6°C. The mean tympanic temperatures taken from the upper ear and the second measurement from the lower ear had a mean of 37.3°C. Mean rectal temperature was also 37.3°C. The mean difference between the two ears was 0.39°C (95% confidence interval, 0.22 to 0.56). This difference disappeared after a while when the patient has been lying on one ear, especially in children, neither this effect nor its magnitude is well known.

In our opinion, a systematic error of 0.4°C to 1.7°C (fig 1).

Comment

Our study showed a clinically significant difference between tympanic temperature measurements in the two ears after a stroke patient had been lying on one ear. This difference disappeared after a while when the patient was no longer lying on one ear. There was no relation between actual body temperature and the size of the measurement error. Although the manufacturer of the tympanic thermometer cautions against hearing of the auditory canal when the patient has been lying on one ear, especially in children, neither this effect nor its magnitude is well known.

In our opinion, a systematic error of 0.4°C on average is not acceptable from a clinical point of view. It may lead to unnecessary investigations and treatment with antibiotics in a considerable number of patients; moreover, an error of this size could have decreased the statistical power of clinical trials of temperature lowering treatment in acute stroke patients, if tympanic temperature was used without attention being paid to the side the patient was lying on.

BOOK REVIEW

Brain fiction, self-deception and the riddle of confabulation

The striking neuropsychological symptom of confabulation represents a prototypical form of false remembering and as such has stimulated great interest among neurologists, psychiatrists, and neuropsychologists. Brain Fiction by William Hirstein is the first book to place confabulation at the centre of its attention. By doing so, Hirstein is faced with the challenge of presenting and examining the various discussions surrounding the definition, the subtypes, the neural, and cognitive basis of confabulation and the relation between its various forms and manifestations. Brain Fiction, however, has taken up further challenges. By borrowing and integrating data and notions from both neuroscience and epistemology, Hirstein aims forward an original definition and model of confabulation, as a dynamic interplay of creative and “checking” mental processes. More generally, Hirstein chooses confabulation as a promising template for the formulation of an interdisciplinary dialogue and interchange of ideas between neuroscience, psychology, and philosophy. In addition, the book proposes to hold a place for confabulation in a continuum of behaviours, ranging from “normal” other, and self-deception attempts in everyday life to deficits of theory of mind, awareness, and symptoms of sociopathy.

It should be evident from the above, that Brain Fiction is addressed to professionals of diverse fields and Hirstein has tried to accommodate the potential clefs in acquaintance with expert knowledge and technical terms. However, the specialised reader should keep in mind that the book does not offer an examination exhaustive in content or encyclopaedic in format. The book is of limited interest to clinicians. It mainly aims at disentangling confabulation from the strict boundaries of its hitherto neuroscientific examination and exposing it to direct philosophical enquiry. This is an endeavour that promises mutual introduction. Yet the author, perhaps motivated by the existing lack of theoretical and descriptive consensus on the subject, also chooses to propose a new aetiological account of the phenomenon in neuroscientific terms. However, the specialized reader should keep in mind that the book does not offer an examination exhaustive in content or encyclopaedic in format. The book is of limited interest to clinicians. It mainly aims at disentangling confabulation from the strict boundaries of its hitherto neuroscientific examination and exposing it to direct philosophical enquiry. This is an endeavour that promises mutual introduction. Yet the author, perhaps motivated by the existing lack of theoretical and descriptive consensus on the subject, also chooses to propose a new aetiological account of the phenomenon in neuroscientific terms. Inevitably, this analysis often entails smoothing of the hard edges of some conflicting neuroscientific findings, and partial coverage of some complex issues raised by confabulation, such as its implications for theories of consciousness, self-formation, and motivation. Such selectivity though has noteworthy benefits. The book introduces an unprecedented emphasis in the study of confabulation by placing the definition, taxonomy, and implications of the phenomenon into epistemological perspective. Thus, it sets the ground for fruitful neuro-philosophical discussions and it refreshes the way neurologists, psychiatrists, and psychologists view this and other related symptoms.

A Fotopoulou

Figure 1 Difference in tympanic temperature taken from the upper and lower ear, plotted against the average tympanic temperature taken from both ears (Bland–Altman plot). The solid horizontal line in the centre indicates the mean difference between the tympanic temperatures (0.39°C), while the dashed horizontal line indicates no difference (the null hypothesis).
