ABSTRACT

Background Mental health issues have been reported after SARS-CoV-2 infection. However, comparison to prevalence in uninfected individuals and contribution from common risk factors (eg, obesity and comorbidities) have not been examined. We identified how COVID-19 relates to mental health in the community-based COVID Symptom Study.

Methods We assessed anxiety and depression symptoms using two validated questionnaires in 413,148 individuals between February and April 2021; 26,998 had tested positive for SARS-CoV-2. We adjusted for physical and mental prepandemic comorbidities, body mass index (BMI), age and sex.

Findings Overall, 26.4% of participants met screening criteria for general anxiety and depression. Anxiety and depression were slightly more prevalent in previously SARS-CoV-2-positive (30.4%) vs SARS-CoV-2-negative (26.1%) individuals. This association was small compared with the effect of an unhealthy BMI and the presence of other comorbidities, and not evident in younger participants (<40 years). Findings were robust to multiple sensitivity analyses. Association between SARS-CoV-2 infection and anxiety and depression was stronger in individuals with recent (<30 days) versus more distant (>120 days) infection, suggesting a short-term effect.

Interpretation A small association was identified between SARS-CoV-2 infection and anxiety and depression symptoms. The proportion meeting criteria for self-reported anxiety and depression disorders is only slightly higher than prepandemic.

INTRODUCTION

Studies from previous coronaviruses suggesting an increased risk of neurological disorders, and case studies and findings regarding the impact of SARS-CoV-2 infection on the central nervous system led to the hypothesis that anxiety/depression symptoms may be more prevalent in individuals after SARS-CoV-2 infection. Indeed, several reports suggest that COVID-19 survivors are at increased risk of mood and anxiety disorders 3 months postinfection. Moreover, the Office for National Statistics reported a steep increase in anxiety/depression symptoms in the general public (irrespective of infection status) compared with prepandemic data, adjusting for socioeconomic factors.

Quantifying the relationship of SARS-CoV-2 infection on anxiety/depression symptoms per se requires disentangling the consequences of infection from other factors such as lockdown measures. Direct links to health records may enable assessment of SARS-CoV-2 infection on psychiatric diagnoses; however, it takes time and resources to acquire large cohorts for such longitudinal studies. Alternatively, analysis of self-reported real-time data allows for faster and timely insights into effects on mental health from SARS-CoV-2 infections.

This study aimed to assess prevalence of anxiety/depression symptoms in individuals with and without prior SARS-CoV-2 infection using a large community cohort, including assessment of other known mental health predictors. We used data from 413,148 tested non-healthcare workers who answered a mental health survey between February and April 2021 via the COVID Symptom Study app.

METHODS

Sample

Data were acquired by the COVID Symptom Study app, a mobile application developed by health data company Zoe Limited in collaboration with King’s College London (KCL), the Massachusetts General Hospital, Lund University and Uppsala University. The app was launched on 24 March 2020 and allows users to report their health status (whether symptomatic or asymptomatic), SARS-CoV-2-related testing and results, and vaccination details, daily. On registration, app users provide demographic and clinical data including age, height, weight, sex, comorbidities (ie, cancer, diabetes, eczema, heart disease, lung disease, kidney disease and hay fever) and healthcare worker status. The app contains can also be modified to address arising research questions. We used data from 413,148 non-healthcare worker users who answered a mental health survey between February and April 2021 and reported a SARS-CoV-2 test result. Healthcare workers were excluded from this analysis due to their likely differing pandemic experience.
Measures
Between 23 February 2021 and 12 April 2021, app contributors were invited to answer a survey about their mental health. Anxiety/depression symptoms were measured using the Generalised Anxiety Disorder assessment-2 (GAD-2) and the Patient Health Questionnaire-2 (PHQ-2). These measures examine symptoms in the preceding 2 weeks, each using two questions. For each question regarding frequency of a proposed situation/feeling, users can answer ‘not at all’, ‘several days’, ‘more than half the days’ or ‘nearly every day’. Each answer scores from 0 for ‘not at all’ to 3 for ‘nearly every day’. Each questionnaire has a score ranging from 0 to 6. Previous studies have shown an association with a positive SARS-CoV-2 result. A total of 26998 positive tests were PCR or lateral flow results; positive antibody tests (8829) were excluded as time of infection was unknown.

RESULTS
Between 23 February and 12 April 2021, 421 977 non-healthcare workers (aged 18–99 years, BMI 15–53) answered the mental health survey and logged a SARS-CoV-2 test result (386 150 negative, 35 827 positive). A total of 26 998 positive tests were PCR or lateral flow results; positive antibody tests (8829) were excluded as time of infection was unknown.

Of the total participants, 26.4% (109 116) scored ≥3 in either GAD-2 or PHQ-2. Participants with anxiety/depression symptoms were younger, had more comorbidities and were more often female, compared with unaffected individuals. Among those predicted to have anxiety or depression (based on a score of ≥3 on GAD-2 or PHQ-2), 38.06% (41 525) reported a previous diagnosis of a prepanademic mental health disorder and 5.79% (6320) reported a learning disability. The study population’s demographic characteristics are presented in Table 1.

SARS-CoV-2 infection was associated with anxiety/depression symptoms (OR 1.08, 95% CI 1.07 to 1.10, p<0.001). However, stronger associations with anxiety/depression symptoms were observed for unhealthy BMI categories (ie, underweight, overweight and obese) with ORs of 1.26 (95% CI 1.22 to 1.30, p<0.001), 1.21 (95% CI 1.20 to 1.22, p<0.001) and 1.61 (95% CI 1.59 to 1.62, p<0.001), respectively. Participants reporting one or more comorbidities (OR 1.25, 95% CI 1.24 to 1.26, p<0.001), and those with learning disabilities (OR 1.35, 95% CI 1.25–1.44, p<0.001) were more likely to report anxiety/depression symptoms.

BMI, body mass index.
1.33 to 1.37, p<0.001) were more likely to have anxiety/depression symptoms. Individuals reporting a previously diagnosed mental health condition had the highest odds of reporting anxiety/depression symptoms (OR 2.26, 95% CI 2.24 to 2.28, p<0.001) (figure 1).

We observed no significant difference in the small overall increased odds of anxiety/depression symptoms with SARS-CoV-2 infection in those with a history of prior mental health conditions (OR 1.09, 95% CI 1.06 to 1.12, p<0.001) and those without such prior history of (OR 1.09, 95% CI 1.07 to 1.10, p<0.001).

Stratification by age group showed no association between a positive SARS-CoV-2 test and anxiety/depression symptoms in young groups (<40 years). Other variables (sex, comorbidities and BMI) were consistent in age-stratified analyses. Finally, in the 26998 cases positive for SARS-CoV-2 by PCR and lateral flow, we tested whether elapsed time after a positive test affected mental health. The relationship between SARS-CoV-2 and anxiety/depression symptoms changed over time, with increased risk of anxiety/depression symptoms in those diagnosed <30 days compared with those diagnosed >120 days prior to the survey (OR 1.15, 95% CI 1.10 to 1.2, p<0.001).

**DISCUSSION**

In this large, community-based study, we report a small positive association between SARS-CoV-2 infection and anxiety/depression symptoms. However, this was dwarfed by associations with the known risk factors BMI, sex and comorbidities. Results were robust to sensitivity analyses stratifying by prior mental health disorder diagnoses. Further, no association between SARS-CoV-2 infection and anxiety/depression symptoms was found in younger age groups (<40 years).

Association between SARS-CoV-2 infection and anxiety/depression symptoms changed over time, with the strongest association in those infected <30 days prior to the survey, suggesting a short-term effect of infection on mental health only. It is possible that other factors affecting mental health which were changing over the pandemic (e.g., lockdown) may moderate an effect of elapsed time since SARS-CoV-2 infection on mental health.21
Overall prevalence of anxiety/depression symptoms in our study (26.4%) is slightly increased compared with prepan-
demic levels of mental health issues in the UK general popu-
lation assessed by the UK Household Longitudinal Study with the
GHQ-12 questionnaire (18.9% in 2018\textsuperscript{22} but broadly compa-
rible to the level seen in April 2021 (27.3%)\textsuperscript{25}. This previous
2021 study did not explore any relationship with SARS-CoV-2
infection. A recent analysis of 1112 subjects experiencing prob-
cable COVID-19 symptoms suggested a positive association
between COVID-19 and anxiety/depression symptoms 1–7
months after suggested infection (OR 1.31–1.47).\textsuperscript{2} Our study
benefits from a much larger sample size of tested participants.

Our study has several limitations. Data are self-reported
using a mobile app and may disproportionately represent more
affluent populations. We only had one time point of mental
health data collection, limiting our ability to test if associations
changed as the pandemic progressed. Additionally, although we
applied weighting for the probability of being tested for the virus,
results referring to time since testing might be still biased due to
limited testing capacity early in the pandemic. As in any study
assessing mental health through questionnaires, selection bias
(wherby mental health influences who responds) and reporting
bias (relating to perception and/or influence of a ‘valid’ reason
to report) may limit the validity of our results. Further analyses
of longitudinal datasets with different reporting structures are
warranted.

CONCLUSION
This study suggests a weak association between SARS-CoV-2
infection and anxiety/depression symptoms, especially in adults
aged 40 years, which is small relative to known risk factors
such as previous medical or mental health conditions and/or
unhealthy BMI. The association was most evident in recently
infected individuals. This suggests that an effect of SARS-CoV-2
on mental health may be of short duration. Further explo-
ration may help to understand factors that will improve mental
health after SARS-CoV-2 infection.
