Misdiagnosis of prolonged psychogenic non-epileptic seizures as status epilepticus: epidemiology and associated risks

Johannes Jungilligens, Rosa Michaelis, Stoyan Popkirov

ABSTRACT

Objective To determine the epidemiology of prolonged psychogenic non-epileptic seizures (pPNES) misdiagnosed as status epilepticus, as well as the risks associated with non-identified treatment.

Methods We performed an individual patient data analysis from the Rapid Anticonvulsant Medication Prior to Arrival Trial (RAMPART) and the Established Status Epilepticus Treatment Trial (ESETT) to assess incidence, patient characteristics and clinical course of misdiagnosed pPNES.

Results Among 980 patients aged 8 years or older diagnosed and treated for status epilepticus in RAMPART and ESETT, 79 (8.1%) were discharged with a final diagnosis of pPNES. The relative incidence was highest in adolescents and young adults (20.1%). The typical female preponderance seen in that age bracket was not evident in children and older adults. Adverse effects, including respiratory depression and intubation, were documented in 26% of patients with pPNES receiving benzodiazepines in RAMPART and 33% of patients receiving additional second-line medication in ESETT. In ESETT, patients who were treated with benzodiazepines before hospital admission had higher rates of unresponsiveness and severe adverse effects than those treated after admission, suggesting cumulative effects of accelerated treatment momentum. Across trials, one in five patients with pPNES were admitted to an intensive care unit.

Conclusions Misdiagnosis and treatment of pPNES as status epilepticus are a common and widespread problem with deleterious consequences. Mitigating it will require training of emergency staff in semiological diagnosis. Status epilepticus response protocols should incorporate appropriate diagnostic re-evaluations at each step of treatment escalation, especially in clinical trials.

INTRODUCTION

Status epilepticus is thought to cause irreversible harm after more than 30 min of ongoing convulsions, so early aggressive treatment is recommended by most guidelines. Within minutes, benzodiazepines should be administered as first-line medication, with high-dose antiepileptic drugs and intubation as second-line and third-line treatment in cases of refractory seizure activity. This compression of treatment timeframes has proven beneficial for the majority of patients with status epilepticus. However, this treatment imperative can come at the cost of diagnostic accuracy in emergencies.

The main differential to consider when assessing patients with suspected (convulsive) status epilepticus are dissociative seizures, also known as functional or psychogenic non-epileptic seizures (PNES). Prolonged PNES (pPNES) are reported by 78% of patients with PNES and lead to emergency admissions to the intensive care unit (ICU) in 18%–27% of patients. Acute pharmacological treatment is not indicated as pPNES are usually self-limited and do not respond to medication (beyond the occasional placebo response or deep sedation). pPNES generate no direct secondary physical harm to patients and should be treated with verbal and behavioural interventions only.

As clinical differentiation between epileptic seizures and PNES requires specific semiological expertise, and the treatment imperative for presumed status epilepticus demands almost immediate decision-making, misdiagnosis is common in emergency settings and PNES are often treated mistakenly with non-identified medication. Retrospective reviews suggest that patients with misdiagnosed pPNES often require benzodiazepines (at even higher doses than patients with status epilepticus) and frequently require endotracheal intubation as a consequence. Of note, pPNES are the foremost determinant of healthcare utilisation costs in patients with PNES.

A systematic look at treatment trials for status epilepticus presenting to emergency services (table 1, online supplemental figure 1) reveals that misdiagnosis of pPNES as status epilepticus occurs in various settings and at all levels of treatment: prehospital and in the emergency department; and first-line and second-line therapy. Misdiagnosis is common in both adult and paediatric populations and in both paramedic-led and physician-led emergency services. Remarkably, none of the listed trials had specific procedures in place to recognise and exclude pPNES from study enrolment, nor did they specify protocols for treatment reallocation in cases of misdiagnosis.

To better understand the epidemiology of pPNES misdiagnosed as status epilepticus as well as the risks of harm from non-identified treatment, we performed an individual patient data analysis from the two largest status epilepticus treatment trials to date: the Rapid Anticonvulsant Medication Prior to Arrival Trial (RAMPART) and the Established Status Epilepticus Treatment Trial (ESETT). We then discuss strategies that may improve recognition of pPNES within emergency medical services.
and offer recommendations to improve future status epilepticus response protocols in clinical practice and treatment trials.

METHODS

We analysed available primary data from the two largest status epilepticus treatment trials to date. RAMPART (ClinicalTrials.gov identifier: NCT00809146) is a randomised, double-blind trial comparing intramuscular versus intravenous benzodiazepine as first-line therapy for status epilepticus, which comprised 1023 cases from 893 patients enrolled between June 2009 and January 2011. After excluding cases with eligibility violations, incorrect study medication/dose assignment, repeated enrolment, etc (see original publication for details), 732 patients were included in the final per-protocol analysis. In addition, we analysed data of ESETT (ClinicalTrials.gov identifier: NCT01960075), which comprises 478 cases from 462 patients treated for status epilepticus at 39 different study centres, which comprises 478 cases from 462 patients enrolled between November 2015 and December 2018 at 58 hospital emergency departments across the USA.16 17 ESETT is a randomised, double-blind study to compare the effectiveness of levetiracetam, fosphenytoin and valproate in patients with established status epilepticus unresponsive to treatment with benzodiazepines. Thus, we base our analysis on data from combined 1210 individual patients. We focus on patients who were discharged with a final diagnosis of non-pPNES. Thus, we base our analysis on data from combined 1210 individual patients. We focus on patients who were discharged with a final diagnosis of non-pPNES. Among 1210 patients diagnosed and treated as status epilepticus, 980 were aged eight years or older. Of these patients, 79 (8.1%) were discharged with a final diagnosis of pPNES. Of these, 53 (70%) were female and the mean age was 32.6 years (SD: 15.9 years), ranging from eight to 84 years.

Compared with patients with status epilepticus, the relative prevalence of pPNES across age groups was significantly different ($\chi^2(10) = 66.838$, $p < 0.001$), indicating a significant association between age and diagnosis (figure 1). The relative prevalence of pPNES was highest among adolescents and younger adults aged 15–29 years, with 20.1% of these patients (38 of 189) eventually recognised as having had pPNES. Patients with pPNES were misdiagnosed and mistakenly treated for status epilepticus at 39 different study centres, confirming that this is a widespread phenomenon.

RESULTS

Among 1210 patients diagnosed and treated as status epileptic, 980 were aged eight years or older. Of these patients, 79 (8.1%) were discharged with a final diagnosis of pPNES. Of these, 53 (70%) were female and the mean age was 32.6 years (SD: 15.9 years), ranging from eight to 84 years.

Compared with patients with status epilepticus, the relative prevalence of pPNES across age groups was significantly different ($\chi^2(10) = 66.838$, $p < 0.001$), indicating a significant association between age and diagnosis (figure 1). The relative prevalence of pPNES was highest among adolescents and younger adults aged 15–29 years, with 20.1% of these patients (38 of 189) eventually recognised as having had pPNES.

Patients with pPNES were misdiagnosed and mistakenly treated for status epilepticus at 39 different study centres, confirming that this is a widespread phenomenon.

First-line treatment

Regarding the effects of first-line treatment with benzodiazepines, the 46 patients with pPNES from the RAMPART data were analysed. In 14 (30%) patients, prehospital study medication (10 mg intramuscular midazolam plus intravenous placebo, or 4 mg intravenous lorazepam plus intramuscular placebo) was not followed by seizure termination within 10 min or before arrival at the hospital (primary endpoint). On hospital arrival, seven (15%) patients were directly admitted to the ICU, while twelve (26%) patients were admitted to a non-ICU unit and 27 (59%) patients were discharged directly from the emergency department. Those admitted to the ICU remained there for a median of one day (range 1–7 days). Overall, the hospital stay of admitted patients had a median duration of three days (range 1–7 days).

In twelve (26%) patients, a total of 17 adverse events were recorded (online supplemental table S1 presents an overview of all adverse events and their grading across RAMPART and ESETT patients). One of these events—a case of respiratory depression—was reported as being possibly related to the study intervention and led to intubation.

ESETT, Established Status Epilepticus Treatment Trial; ns, not specified; pPNES, prolonged psychogenic non-epileptic seizures; RAMPART, Rapid Anticonvulsant Medication Prior to Arrival Trial.

rated as ‘serious’. Four events were reported as being likely
recorded (online supplemental table S1), four of which were
unarousable at this point.

Agitation Sedation Scale was administered at the 60 min assess-
mint (table
was still not improved in nine patients (27%). The Richmond
Agitation Scale had clinically apparent seizures (9%), while responsiveness
to verbal or noxious stimuli was not improved in
eleven (33%) patients. At the 60 min assessment, three patients
were medicated in-
hospital. Ten patients (31%) were admitted to the ICU and remained there for up to twelve days (median: one day). Twelve patients (36%) were admitted to a non-ICU unit, and eleven (33%) were discharged directly from the emergency
department. Overall, the hospital stay of admitted patients had a median duration of one day (range 1–12 days).

All patients were assessed for seizure manifestations and
responsiveness at 20 and at 60 min after the start of the study
drug administration. At 20 min assessment, clinically apparent
seizures were observed in nine (27%) patients; at that time, responsiveness to verbal or noxious stimuli was not improved in eleven (33%) patients. At the 60 min assessment, three patients
still had clinically apparent seizures (9%), while responsiveness
was still not improved in nine patients (27%). The Richmond
Agitation Sedation Scale was administered at the 60 min assess-
ment (table 2). Nine patients (27%) were deeply sedated or
unarousable at this point.

In eleven (33%) patients, a total of 13 adverse events were
recorded (online supplemental table S1), four of which were
rated as ‘serious’. Four events were reported as being likely
related to the study intervention: abdominal pain, hypersensi-
tivity, hypotension and pruritus. The adverse events were graded
as more severe in patients who received benzodiazepines before
emergency department arrival than those who did not (Fisher’s
exact test=10.455, p=0.033). In two patients (6%), endotracheal intubation was performed. The adverse events leading to
intubation were documented as ‘depressed level of conscious-
ness’ in one case and ‘cerebrovascular accident’ in the other case.

**DISCUSSION**

In this individual patient data analysis from the two largest status
epilepticus trials to date, we found that among patients aged 8
or older the overall rate of misdiagnosed pPNES was 8.1% and
up to 20.1% in adolescents and young adults. This age group
also showed the typical female preponderance for PNES, while
gender distribution tended to equalise in children and older
adults, in line with previous observations. The annual inci-
dence of confirmed status epilepticus presenting to the emer-
gency department is reported as 16 per 100 000. Based on
our analysis, the extrapolated incidence of misdiagnosed pPNES
receiving non-indicated medication can be conservatively esti-
mated at around 1.3 per 100 000 inhabitants per year, which
is equal to that of cerebral venous and sinus thrombosis in the
general population.

As treatment is required to commence as soon as 5 min after
seizure onset, a certain degree of aetiology-agnostic emergency
decision-making can be encountered in response algorithms for
ongoing seizures (i.e., ‘shoot first, ask questions later’). Two
common misconceptions might contribute to this approach: (1)
benzodiazepines will also be helpful for PNES, and (2) poten-
tial adverse effects of benzodiazepines and further escalation of
treatment are negligible. Our analysis clearly disproves both of
these assumptions. Benzodiazepine treatment does not reliably
terminate seizure activity, as 30% of RAMPART patients with
pPNES had ongoing seizures after receiving the study medica-
tion. Adverse effects in RAMPART were reported in 26% of
patients with pPNES, including respiratory depression requiring
intubation. By design, all participants in ESETT had ongoing
seizures despite substantial doses of benzodiazepines at the time
of study enrolment, further demonstrating that benzodiazepines
should not be expected to effectively halt PNES. Moreover, 27%
of patients with pPNES in ESETT remained deeply sedated at
1 hour after second-line treatment. Although benzodiazepines
are not known to cause central apnoea, they depress genio-
glossus activity and can lead to obstructive apnoea requiring
intubation. Obesity-related obstructive breathing disorders
are common in patients with PNES, so this poses a particular
danger in this patient group.
Admission to the ICU was necessary in 15% of patients with pPNES in RAMPART and twice that rate in ESETT (31%). The experience of being treated in an ICU can be highly distressing in itself and can lead to ICU-related post-traumatic stress disorder at a significant rate. Known risk factors for this are premorbid depression, negative emotionality, treatment-seeking behaviours and benzodiazepine sedation, revealing a particularly dangerous constellation for patients with pPNES. Moreover, some patients with pPNES were eventually intubated in both trials, an ultimate treatment escalation which has been reported at high rates previously and harbours well-known risks of its own.

An interesting observation regarding the momentum of the status epilepticus treatment imperative could be made from the ESETT data: patients who were treated with benzodiazepines before arrival at the emergency department had higher rates of unresponsiveness and severe adverse effects in the course of treatment and were more likely to be intubated than those treated in-hospital only. This could be explained by more severe seizure manifestations at onset, but alternatively prehospital interventions might accelerate the momentum of treatment, leading to higher medication doses overall and lowering the threshold for treatment escalation. It is worth noting that invasive overtreatment of pPNES can be potentially lethal. In a recent cohort study, patients with video EEG-confirmed PNES (and no sign of comorbid epilepsy) had a more than doubled standardised mortality ratio, and the cause of death was documented as ‘epilepsy’ in 13 of 55 cases (24%), suggesting the possibility of misdiagnosis and associated iatrogenic harm. Therefore, the trade-off between early and aggressive treatment to terminate persistent epileptic seizure activity and investing time to rule out or confirm the possibility of pPNES to avoid iatrogenic harm must be weighed carefully.

Another factor underlying the ‘shoot first’ mentality of convulsive status treatment is the purported lack of reliability of semiological seizure diagnosis. Indeed, semiology alone can be insufficient for a firm diagnosis for many types of seizures and seizure-like events. However, suspected convulsive status epilepticus has pronounced motor symptoms, allowing for a confident diagnosis on clinical grounds in most cases. A recent study on smartphone video recordings of seizures found that convulsive PNES can be identified with 96% accuracy on video. Moreover, examination of ongoing seizures allows for quick assessment of interactive responsivity (e.g., resistance to eye-opening, preservation of pupillary and eyelash reflexes, change in seizure intensity in response to others), which can offer near-absolute specificity for PNES. Filming an ongoing seizure for later specialist evaluation should be encouraged as a critical diagnostic manoeuvre, revealing a particularly dangerous constellation for patients with pPNES. Lastly, some patients with pPNES were eventually intubated in both trials, an ultimate treatment escalation which has been reported at high rates previously and harbours well-known risks of its own.
