ABSTRACT

Objective To compare the disease course in patients with mild Guillain-Barré syndrome (GBS) who were treated with intravenous immunoglobulin (IVIg) or supportive care only.

Methods We selected patients from the prospective observational International GBS Outcome Study (IGOS) who were able to walk independently at study entry (mild GBS), treated with one IVIg course or supportive care. The primary endpoint was the GBS disability score four weeks after study entry, assessed by multivariable ordinal regression analysis.

Results Of 188 eligible patients, 148 (79%) were treated with IVIg and 40 (21%) with supportive care. The IVIg group was more disabled at baseline. IVIg treatment was not associated with lower GBS disability scores at 4 weeks (adjusted OR (aOR) 1.62, 95% CI 0.63 to 4.13). Nearly all secondary endpoints showed no benefit from IVIg, although the time to regain full muscle strength was shorter (28 vs 56 days, p=0.03) and reported pain at 26 weeks was lower (n=26/121, 22% vs n=12/30, 40%, p=0.04) in the IVIg treated patients. In the subanalysis with persistent mild GBS in the first 2 weeks, the aOR for a lower GBS disability score at 4 weeks was 2.32 (95% CI 0.76 to 7.13). At 1 year, 40% of all patients had residual symptoms.

Conclusion In patients with mild GBS, one course of IVIg did not improve the overall disease course. The certainty of this conclusion is limited by confounding factors, selection bias and wide confidence limits. Residual symptoms were often present after one year, indicating the need for better treatments in mild GBS.

INTRODUCTION

Approximately 20%–40% of patients with Guillain-Barré syndrome (GBS) do not lose the ability to walk unaided during their disease course, which has been called ‘mild GBS’.1,2,3 In contrast to what its name suggests, mild GBS may have an unfavourable clinical course and poor outcome after supportive care alone. Patients who initially have mild GBS can deteriorate later on during the progressive phase of the disease. Dilemmas about whether and when to start treatment arise during the first weeks after onset of GBS because currently it is not possible to predict at presentation who is at risk of further deterioration, while postponing treatment until after further deterioration might result in more severe and possibly irreversible nerve damage.4–5 In addition, the differentiation between mild and severe GBS is based on the GBS disability scale, which is mainly driven by motor function of the legs and ignores involvement of the arms as well as cranial, sensory and autonomic nerves or non-motor function; up to 38% of mildly affected patients report residual fatigue, pain or persistent neurological deficits after 6 months.6

Both plasma exchange (PE) and intravenous immunoglobulin (IVIg) are equally effective in GBS patients who are unable to walk independently (severe GBS).7–10 One trial showed that the time to onset of motor recovery in patients still able to walk was shortened after two sessions of PE,1 but no randomised controlled trials have been performed to evaluate the efficacy of IVIg in mild GBS.7,11 Reasons not to treat mild GBS patients may include spontaneous recovery in a large proportion of patients due to the self-limiting nature of the disease, side effects including allergic reactions or thromboembolic events, and the fact that IVIg is expensive.12

A previous study of patients recruited in the International GBS Outcome Study (IGOS) showed that 75% of those with mild GBS at entry were treated with IVIg.13 We have taken advantage of this variation in current treatment practice to compare the clinical course and outcome in patients with mild GBS treated with either supportive care or supportive care and IVIg.

METHODS

International GBS Outcome Study

IGOS is an international, observational, prospective cohort study enrolling patients with GBS from participating centres within 2 weeks of disease onset.14 All patients gave written informed consent.
IGOS cohort: n = 1300

Alternative diagnosis
n = 71 (56)
Protocol violation
n = 6 (4.4)
Incomplete data
n = 10 (7.7)

Patients from Bangladesh
n = 189 (35%

Variant forms without limb weakness
n = 115 (9%)

Patients eligible to determine GBS disability score at entry
n = 909

GBS disability score > 2 at entry
n = 706 (78%)

GBS disability score > 2 at nadir
n = 311 (34%)

Patients with mild GBS at entry
n = 153 (21%)

Treated with PE n = 5

Patients eligible for this study
n = 188

Supportive care
n = 40 (21%)
IVlg group
n = 148 (79%)

Neuromuscular

Study population
From the first 1300 patients enrolled in IGOS (IGOS-1300 cohort), we selected all patients with a GBS disability score of 2 or lower (able to walk independently) at study entry who had been included up until January 2017, with the following exceptions. We excluded patients from low-income countries (ie, Bangladesh) because the current treatment practice differs substantially from other IGOS-participating countries.2 We also excluded patients who had Miller Fisher syndrome and other GBS variants without limb weakness because these variant forms may not affect the GBS disability score or the Medical Research Council (MRC) sum score. We also excluded those who were treated with PE only.

We selected patients with mild GBS at presentation because in clinical practice, the dilemma of whether and when to start treatment is most pressing at the time of initial diagnosis.

Patient groups
We divided patients into those receiving supportive care alone and those receiving supportive care and one standard course of IVlg (2 g/kg in 2–3 days) within the first 4 weeks after study entry. Patients who received additional IVlg courses or PE sessions were not excluded.

We first analysed patients with mild GBS at entry. However, this analysis might have included patients who presented early, but were destined to progress to severe GBS. Therefore, to assess

Assessments
We prospectively collected data regarding age, gender, reported antecedent events and the following clinical features: cranial nerve involvement, sensory deficits, MRC sum score, ataxia, GBS disability score, GBS clinical variant, and autonomic dysfunction at entry and after 1, 2, 4, 8, 13, 26 and 52 weeks. The GBS disability score measures disability, and ranges from 0 (healthy) to 6 (dead).13 The MRC sum score measures strength in six bilateral muscle pairs and ranges from 60 (full muscle strength) to 0 (complete paralysis).16 The presence of autonomic dysfunction was determined by the treating physician, and was defined as cardiac, blood pressure, gastroenterological, bladder, pupil or other autonomic dysfunction. We classified the first Nerve Conduction Study (NCS) according to Hadden’s criteria into the categories demyelinating, axonal, inexcitable, equivocal or normal nerve conduction.17 Treatment information included treatment type (IVlg, PE, other), treatment regimen, dates of start and end of treatment and adverse events.

Study endpoints
The primary endpoint was functional outcome, defined as a lower GBS disability score after 4 weeks in patients treated with one IVlg course compared with patients not treated with IVlg. This endpoint has often been used in previous trials and enables comparisons between studies.7 11 18 19 Secondary endpoints were: GBS disability score at 26 weeks, MRC sum score, Rasch-Built Overall Built Disability Score (R-ODS), fatigue severity scale and the EuroQol Visual Analogue Scale at 4 and 26 weeks, time to regain full muscle strength (MRC sum score of 60), time to reach full disability recovery (GBS disability score of 0),20 21 and the frequency of hospital admission, progression to GBS disability score 3 or higher, progression to mechanical ventilation, and the presence of pain and cranial nerve deficits at 4 and 26 weeks.22 The R-ODS raw score was transformed into the R-ODS centile metric score to calculate the median R-ODS centile metric.20 A mild course during the 4 weeks of follow-up was defined as a GBS disability score of 2 or lower at study entry and after 1, 2 and 4 weeks. The time needed to regain full muscle strength (MRC sum score of 60 points) and full recovery on the GBS disability scale (a score of 0 points) were derived from the study assessment dates. Residual symptoms were defined as the presence of pain (muscle, joint, radicular, neuropathic pain, painful paresthesias), cranial nerve involvement, sensory deficits, ataxia or an MRC sum score <60 after 1-year follow-up. Complications (not further specified), number of treatment related fluctuations (TRFs) and mortality were also recorded.

Statistical analysis
For statistical analyses we used SPSS software (V.21.0 and V.24.0). Data were expressed as medians with IQR or as proportions. We used Mann-Whitney U test to compare continuous variables across two groups, and χ² or Fisher’s exact tests to compare proportions. A two-sided p < 0.05 was considered statistically significant. We assessed the effect of IVlg on the GBS disability scale at 4 and 26 weeks by a multivariable ordinal regression model, where we corrected for known prognostic and imbalanced factors (age, ataxia, autonomic dysfunction, GBS disability score and MRC sum score at entry, preceding diarrhoea,

Figure 1 Flow chart study population. *Variant forms without limb weakness (n = 115): pure MFS: n = 66; sensory ataxic GBS: n = 24; other variant forms without limb weakness: n = 25. points on the MRC sum score during the visits prior to and after 1 week, and for the IVIg group as improving at least two for the supportive care group was defined as improving at least provisionally corrected for the presence of early improvement, which electrophysiological subtype and geographical region). We addi-

**RESULTS**

By January 2017, 1300 patients were enrolled in IGOS with a follow-up period of at least 12 months. We excluded 391 patients (30%): 71 (5%) with an alternative diagnosis, 6 (0.4%) with a protocol violation, 10 (1%) with incomplete data, 189 (15%) from Bangladesh and 115 (9%) who had a variant form of GBS without limb weakness (figure 1). Of the remaining 909 patients, 11 (1%) had a GBS disability score higher than 2 before study entry, and 705 (78%) had a score greater than 2 at study entry, and they were also excluded. The remaining group of 193 patients who presented with a mild form of GBS were treated as follows: 40 (22%) with supportive care alone, 148 (77%) with IVIg and 5 (3%) with PE. Patients who underwent PE only were excluded from this study. Thus 188 patients altogether were included (figure 1). The 148 IVIg treated patients received their IVIg course of 2 g/kg in 2–5 days before or at entry of the study (n=112, 76%) or in the first week after study entry (n=36, 24%).

**Patient characteristics**

There were no differences between the groups in age, gender, reported antecedent events, GBS disability score, MRC sum score, GBS variants, cranial nerve involvement or pain at entry (table 1).

Compared with the untreated patients, the IVIg group more often had ataxia (50/139, 36% vs 7/39, 18%, p=0.03) and autonomic dysfunction (25/142, 17% vs 1/39, 3%, p=0.02). The MRC sum score after 1 week of follow-up did not differ between the groups (IVIg group 56, IQR 50–59 vs the supportive care group 56, IQR 54–58, p=0.51). However, few patients in the IVIg group improved two points on the MRC sum score prior to and after the start of their IVIg (23/132, 17%), whereas improvement from study entry to 1 week often occurred in the supportive care group (14/31, 45%, p=0.001). The GBS disability scores deteriorated slightly after 1 week in the intravenous Ig group in which 41/135 (30%) of the patients had deteriorated at least one point compared with only 5/34 (15%) of the supportive care alone patients (p=0.07, figure 2).

**Primary endpoint**

Treatment with one IVIg course made no difference to the GBS disability score 4 weeks after study entry (figure 2). After correction for prognostic confounders and unbalanced patient characteristics, the adjusted ORs (aOR) for a better outcome at 4 weeks in the IVIg group was 1.62 (95% CI 0.63 to 4.13, p=0.32) (table 2).

**Secondary endpoints**

There was no effect on the GBS disability scale at 26 weeks after IVIg. The aOR for a lower GBS disability score at 26 weeks was 0.65 (95% CI 0.24 to 1.78, p=0.41) (table 2). There was also no favourable effect on any of the other secondary endpoints, although fewer IVIg treated patients reported pain after 26 weeks (26/121, 22%) compared with supportive care patients (12/30, 40%), p=0.04, table 3).

GBS, Guillain-Barré syndrome; IVIg, intravenous immunoglobulin; MFS, Miller Fisher syndrome; MRC, Medical Research Council; na, not applicable; URTI, upper respiratory tract infection.
The median R-ODS centile metric score did not differ between the two groups at 4 weeks (table 3). The time to complete muscle strength recovery was shorter in the IVIg group (28 days, IQR 14–56) than in the supportive care group (56 days, IQR 14–182, p=0.03). However, the Kaplan-Meier analysis at 1-year follow-up did not differ significantly (p log rank=0.26, figure 3A).

Few side effects of IVIg were reported; these included headache (n=8), nausea/vomiting (n=4), venous puncture hazards (n=1), eczema (n=1), blood pressure fluctuations (n=1) and thromboembolism (n=1). Ten patients (7%) experienced a TRF of whom six were treated with either a second IVIg course or PE. Five other patients (3%) received a second IVIg course or additional PE, probably because of ongoing disease progression.

*Adjusted for: age, ataxia at entry, autonomic dysfunction at entry, diarrhoea, region, GBS disability score at entry, MRC sum score at entry, axonal subtype, improvement on the MRC sum score.

GBS, Guillain-Barré syndrome; IVIg, intravenous immunoglobulin; MRC, Medical Research Council.

Neuromuscular despite IVIg. One patient in the IVIg group died 4 weeks from presentation. He was 64 years old, had no medical history, presented with a mild sensorimotor GBS but continued to deteriorate to severe GBS in the first weeks. He received 2 g/kg IVIg in 5 days after admission and was retreated with IVIg 0.8 g/kg in 2 days after 2 weeks, and died 2 weeks later from bilateral pulmonary thromboembolism and a recent left ventricular myocardial infarction.

After 1-year follow-up, the frequency of residual symptoms was similar in both groups, occurring in 44/107 (41%) of the IVIg treated patients and in 11/29 (38%) of the untreated patients (p=0.76). In the total group, residual symptoms most frequently consisted of pain (32/137, 23%), sensory deficits (31/135, 23%), cranial nerve involvement (11/136, 8%) and limb weakness (11/136, 8%).

Subgroup analysis of patients with persistent mild GBS
A further analysis was conducted in those patients with persistent mild GBS for the first 2 weeks (GBS disability score 2 or lower), including 29 patients in the supportive care group and 82 patients in the IVIg group. The baseline characteristics were comparable between the two groups and did not differ from the characteristics of the whole group of patients with mild GBS at study entry (online supplemental appendix table 1). With a multivariable ordinal regression model, the aOR for an improved GBS disability score at 4 weeks was 2.32 in favour of IVIg, but this was not significant (95% CI 0.76 to 7.13, p=0.14). Most of the
secondary endpoints did not improve after IVlg. However, more IVlg treated patients regained full muscle strength after 4 weeks (54/77, 70% vs 12/25, 48%, p=0.04) and the time to regain full muscle strength was shorter in the IVlg treated patients (14 days, IQR 7–28) than in the untreated patients (56 days, IQR 14–182, p=0.01). However, the Kaplan-Meier curves of the two groups displaying the time to regain full muscle strength after 4 weeks were not different (figure 3B). Residual symptoms were frequently and equally present in both groups (supportive care group 9/26 (35%) and IVlg group 20/64 (31%), p=0.76).

**DISCUSSION**

This observational study showed no benefit from IVlg on functional outcome in GBS patients who were able to walk independently at presentation or during the first 2 weeks after study entry. Up to 41% of IVlg treated and untreated patients showed residual symptoms at 1 year.

We have conducted the first comparative study to estimate the efficacy of IVlg in mild GBS. Because of the observational nature of the study, treatment was offered at the discretion of the study investigator. Approximately three-quarters of patients with persistent mild GBS were treated with IVlg, despite the lack of any controlled trial data providing evidence for efficacy of IVlg in mild GBS. Arguments to treat this group in an early phase are that it is currently not possible to predict who is at risk for further deterioration, early treatment may prevent further nerve damage, and the fact that side effects of a standard IVlg course (2 g/kg in 5 days) are infrequent and generally mild. In the subanalysis of persistent mild GBS, the baseline characteristics were comparable, and so the question arises whether clinicians were inclined to treat mild GBS whatever the circumstances or if there were other unobserved factors that resulted in confounding by indication. This phenomenon occurs when a worse disease course is both an indication to start treatment and also a predictor for poor outcome. Another likely confounder is disease progression, which would have been more likely to lead to IVlg treatment compared with those with a stable course or improvement. Of the untreated patients, 14/31 (45%) were lead to IVlg treatment compared with those with a stable course is disease progression, which would have been more likely to

...mild GBS patients at 6 months, irrespective of treatment. We also found that despite the presumed benign course and good outcome, approximately 40% of patients with mild GBS, regardless of IVlg treatment, had residual symptoms at a year. In the subset of those with persistent mild GBS, residual symptoms were present in 35% of patients. This demonstrates the unmet need for more effective treatment even for those considered mildly affected.

The most important limitation of our study is its observational nature resulting in selection bias and confounding by indication. In addition, the most responsive primary endpoint for patients with mild GBS is unknown. As discussed above, onset of motor recovery might be a responsive endpoint, but the IGOS database did not document the date of onset of motor recovery so we could only estimate the time of onset of motor recovery by using the study visit dates. Another possible endpoint might be time to hospital discharge, especially in studies including cost-effectiveness analysis. However, discharge policies differ widely between hospitals and the date of hospital discharge was not recorded in IGOS. For this study, we used the GBS disability scale because it is widely known and most often used in therapeutic trials for GBS. However, the scale may not be sensitive enough for patients with mild GBS. In 2013, a group of inflammatory neuropathy experts reached agreement and recommended using the activity and participation level measured by the 24-item R-ODS for all future therapeutic GBS studies. However, the R-ODS scale contains items which are not always applicable, especially in different regions of the world, diminishing its reliability and applicability. Lastly, although IGOS has collected a very large cohort of GBS patients, the patient numbers in this study, and especially in the substudy of patients with persistent mild GBS, were small, and the study could be underpowered.

Although this observational study did not identify significant benefit from adding IVlg to supportive care in initially mild GBS, confounding factors may have masked the possible positive effect of such treatment. IVlg may shorten time to full recovery of muscle strength and PE has previously been proven to hasten recovery in mild GBS. Since other trials in severe GBS have shown that IVlg and PE have similar efficacy, it would be premature to conclude that PE is more efficacious than IVlg in mild GBS. Because this study has shown that 40% of patients with mild GBS have persistent symptoms at 1 year regardless of treatment status, other more effective treatments are needed. Ideally, future studies would use more responsive clinical outcome measures appropriate for mild GBS, measure prognostic biomarkers of ongoing inflammation and nerve damaging which predict disease progression, and include more participants in a randomised controlled design.

neurological disorders. 

Contributors C.V.: Study concept and design, patient inclusion, acquisition of data, analysis and interpretation of the data, drafted and revised the manuscript for intellectual content. Member of IGOS Coordinating Center, IGOS Country Coordinator. TH: Study concept and design, interpretation of the data, drafted and revised the manuscript for intellectual content. Member of the IGOS Steering Committee. RAVD: Study concept and design, interpretation of the data, drafted and revised the manuscript for intellectual content. Member of the IGOS Steering Committee. PAoD: Study concept and design, interpretation of the data, drafted and revised the manuscript for intellectual content. Member of the IGOS Steering Committee. SK: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. Member of the IGOS Steering Committee. ICG: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. IGOS Country Coordinator. GC: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. IGOS Country Coordinator. DC: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. IGOS Country Coordinator. GC: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. IGOS Country Coordinator. HCL: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. RCR: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. IGOS Country Coordinator. GC: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. DB: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. MPL: Patient inclusion, acquisition of data, interpretation of the data, revised the manuscript for intellectual content. KCG: Interpretation of the data, revised the manuscript for intellectual content. Member of the IGOS Steering Committee, IGOS Country Coordinator. BCI: Study concept and design, patient inclusion, acquisition of data, interpretation of the data, drafted and revised the manuscript for intellectual content. Member of the IGOS Steering Committee, Member of the IGOS Coordinating Center, IGOS Country coordinator.

Funding This study is mainly funded by the Interlaken Leadership Awards 2014 from CSL Behring (ILA-2014, https://www.interlakenleadershipawards.com). Other sponsors of IGOS are the GBS-CIDP Foundation International, grifols, GAIN Charity, Erasmus University Medical Center, Glasgow University, CSL Behring and Annexon.

Competing interests DRC is a consultant to Amgen, Amgen Biosciences, argenx SE, Biostest Pharmaceuticals, Boehringer Ingelheim, Cigna Health Management, CSL Behring, Grifols, S.A., Neupogen, New Enterprise Associates, Octapharma AG, Passage Bio, Pfizer, Pharmexent SAS, Polynourem Pharmaceuticals, Sanofi-Aventis, Seattle Genetics and UCB Pharma. He is a member of Data Safety Monitoring Boards for Alnylam Pharmaceuticals, Anavek Life Sciences, PledPharma AB, Momenta Pharma, Hansa Medical AB and Mitsuibishi Tanabe Pharma Corporation. He receives royalties for Technology Licensing from AstraZeneca Pharmaceuticals, LP, Genentech, Lexicon, Seattle Genetics, Merrimack Pharmaceuticals, Disarm Therapeutics. RACH has consultancies with Hansa Biopharma, Immunic and Sanofi. PAoD has received honoraria for consulting, lectures and serving on steering committees from Octapharma, Kedrion, CSL Behring, Grifols and Hansa (all honoraria to departmental research fund) and received grants from the Princes Beatrice Spierfonds, Sanquin Blood supply, Shire and Grifols for conducting clinical trials in GBS and CIDP. MPL is supported by the by the National Institute for Health Research University College London Hospitals Biomedical Research Centre. KCG has consulting agreements with Annexon, Argexx and UCB Pharma. BCJ has received funding for research projects from Princes Beatrice Spierfonds, Horizon 2020, GBS-CIDP Foundation International, Grifols, CSL Behring, Annexon and Hansa Biopharma. He is on the Medical Advisory Board for the GBS-CIDP Foundation International, and a member of the Inflammatory Neuropathy Consortium.

Patient consent for publication Not required.

Ethics approval The study was approved by the review boards of the Erasmus University Medical Centre, Rotterdam, the Netherlands, and the local institutional review boards of participating hospitals or universities.

Provenance and peer review Not commissioned; externally peer reviewed.

Data availability statement Data are available on reasonable request. Data collected in IGOS will be used initially for planned research projects conducted by the IGOS Consortium. Some data will be made available from the corresponding author on reasonable request.

Supplemental material This content has been supplied by the author(s). It has not been vetted by BMJ Publishing Group Limited (BMJ) and may not have been peer-reviewed. Any opinions or recommendations discussed are solely those of the author(s) and are not endorsed by BMJ. BMJ disclaims any liability and responsibility arising from any reliance placed on the content. Where the content includes any translated material, BMJ does not warrant the accuracy and reliability of the translations (including but not limited to local regulations, clinical guidelines, terminology, drug names and drug dosages), and is not responsible for any error and/or omissions arising from translation and adaptation or otherwise.
